Background: Assessment of programmed cell death-ligand 1 (PD-L1) immunohistochemical staining is used for treatment decisions in non-small cell lung cancer (NSCLC) regarding use of PD-L1/programmed cell death protein 1 (PD-1) immunotherapy. The reliability of the PD-L1 22C3 pharmDx assay is critical in guiding clinical practice. The Cardiopulmonary Pathology Study Group of the Korean Society of Pathologists investigated the interobserver reproducibility of PD-L1 staining with 22C3 pharmDx in NSCLC samples. Methods: Twenty-seven pathologists individually assessed the tumor proportion score (TPS) for 107 NSCLC samples. Each case was divided into three levels based on TPS: < 1%, 1%–49%, and ≥ 50%. Results: The intraclass correlation coefficient for TPS was 0.902 ± 0.058. Weighted κ coefficient for 3-step assessment was 0.748 ± 0.093. The κ coefficients for 1% and 50% cut-offs were 0.633 and 0.834, respectively. There was a significant association between interobserver reproducibility and experience (formal PD-L1 training, more experience for PD-L1 assessment, and longer practice duration on surgical pathology), histologic subtype, and specimen type. Conclusions: Our results indicate that PD-L1 immunohistochemical staining provides a reproducible basis for decisions on anti-PD-1 therapy in NSCLC.

Key Words: Programmed cell death-ligand 1; Reproducibility; Observer variation; Immunohistochemistry

*Sunhee Chang and Hyung Kyu Park contributed equally to this work.
This study aimed to investigate the interobserver reproducibility of assessing PD-L1 expression in NSCLC tissue samples. Furthermore, association with observer factors and reproducibility of PD-L1 assessment was also investigated.

**MATERIALS AND METHODS**

**Study material**

A total of 107 cases of NSCLC were selected from the archives of the Department of Pathology of Samsung Medical Center from October 2016 and December 2016. Of these, 22 tissue samples were from resections, 66 tissue samples were from computed tomography-guided core biopsy, and 19 tissue samples were cell blocks of endobronchial ultrasound-guided transbronchial needle aspirate (EBUS-TBNA). The study material comprised 66 adenocarcinomas, 33 squamous cell carcinomas, and eight other non-small cell lung cancers. Selected tumor samples contained more than 100 cells per sample.

**Immunohistochemical staining and evaluation**

Tissue samples were stained for PD-L1 with the 22C3 pharmDx Kit (Agilent Technologies, Santa Clara, CA, USA) on the Dako Autostainer Link 48 platform (Agilent Technologies). Deparaffinization, rehydration, and target retrieval procedures were performed using EnVision FLEX Target Retrieval solution (1 ×, low pH) and EnVision FLEX wash buffer (1 ×). The tissue samples were then placed on the Autostainer Link 48. This instrument performed the staining process by applying appropriate reagent, monitoring incubation time, and rinsing slides between reagents. The reagent times were preprogrammed in the Dako Link software. A sample with primary antibody omitted was used as a negative control. Samples were subsequently counterstained with hematoxylin and mounted in non-aqueous, permanent mounting media. The stained slides were scanned by an Aperio scanner (Leica Biosystems, Buffalo Grove, IL, USA). Pathologists scored the virtual images using ImageScope software (Leica Biosystems).

Tumor proportion score (TPS) was defined as the percentage of viable tumor cells with any perceptible membrane staining irrespective of staining intensity. Normal cells and tumor-associated immune cells were excluded from scoring. Each case was divided into three levels based on TPS: < 1% (no PD-L1 expression), 1%–49% (PD-L1 expression), or ≥ 50% (high PD-L1 expression) (Fig. 1).

**Fig. 1.** Programmed cell death-ligand 1 (PD-L1) immunohistochemistry results in non-small cell lung cancer patients using 22C3 antibody on fully automated Dako Autostainer Link 48 platform. (A) Negative staining for PD-L1. (B) PD-L1 tumor proportion score (TPS) of 10%. (C) PD-L1 TPS of 70%. (D) PD-L1 TPS of 100%.
Participating pathologists

All slides were independently evaluated by 20 pulmonary pathology specialists and seven surgical pathology fellows. Eleven experts participated in a 1-day training course by Dako (Agilent Technologies, Santa Clara, CA, USA) relating to evaluation of the PD-L1 22C3 assay. Participant practice duration ranged from 1 to 37 years with a median of 13 years. Sixteen of the 27 pathologists gained experience in PD-L1 assessment by practicing daily with two to 500 cases per day for 2 months before starting this study, and four of the 16 pathologists had assessed more than 100 cases.

Statistical analysis

The gold standard PD-L1 TPS was established as TPS and assessed by highly trained and experienced experts. To assess the concordance of TPS between the 27 pathologists and the gold standard, intraclass correlation coefficients (ICCs) were calculated. The weighted kappa (κ) coefficient was calculated to evaluate concordance of the 3-step assessment between pathologists and the gold standard. Agreement for 1% and 50% cut-offs was assessed using overall percent agreement (OPA), positive and negative percent agreement, and Cohen’s κ coefficient. Correlations between TPS and experience for PD-L1 test experience or practice duration were investigated using Spearman’s rank correlation coefficient. Correlations between the 3-step assessment and PD-L1 test experience or practice duration were also investigated using Spearman’s rank correlation coefficient. Differences in the concordance of TPS, 3-step assessment, and 1% and 50% cut-offs were compared between the expert group and fellow group using Wilcoxon rank sum tests. Correlations between TPS or 3-step assessment and histologic subtype or specimen type were assessed using Kruskal-Wallis Test.

An ICC is interpreted as follows: below 0.3 indicates poor agreement, 0.5 indicates moderate agreement, 0.7 indicates strong agreement, and 0.85 or more indicates almost perfect agreement. A κ coefficient of 0.4 or less is poor to fair agreement, greater than 0.4 to 0.6 is moderate agreement, greater than 0.6 to 0.8 is substantial agreement, and greater than 0.8 is almost perfect agreement. Spearman’s rank correlation coefficient is interpreted as follows: below 0.3 indicates little if any (linear) correlation, between 0.3 and 0.5 indicates low correlation, between 0.5 and 0.7 indicates moderate correlation, between 0.7 and 0.9 indicates high correlation, and 0.9 or more indicates very high correlation. A p-value of < .05 was considered statistically significant. Statistical analyses were performed using SAS ver. 9.4 (SAS Institute Inc., Cary, NC, USA).

Ethics statement

This study was approved by the Institutional Review Board of Inje University Ilsan Paik Hospital with a waiver of informed consent (2018-08-009).

RESULTS

Interobserver reproducibility

Among 107 samples, 22 samples (20.6%) had a TPS <1%, 40 samples (37.4%) had a TPS between 1% and 49%, and 45 samples (42.1%) had a TPS ≥ 50%. The ICC for TPS was 0.902 ± 0.058, indicating almost perfect agreement (Table 1). Weighted κ coefficient for the 3-step assessment was 0.748 ± 0.093, indicating substantial agreement. Using ≥ 1% stained tumor cells as the cut-off for a positive test, the κ coefficient was calculated as 0.633 ± 0.058, indicating almost perfect agreement (Table 1). Weighted κ coefficient for the 3-step assessment was 0.748 ± 0.093, indicating substantial agreement. Using ≥1% stained tumor cells as the cut-off for a positive test, the κ coefficient was calculated as 0.633 ± 0.111, and OPA was 86.2 ± 5.5% (Table 2). The κ coefficient was 0.834 ± 0.095, and the OPA was 92.1 ± 4.4% for cut-off ≥ 50%. These results indicate substantial agreement for 1% and almost perfect agreement for 50% cut-offs. The interobserver reproducibility was greater at the 50% cut-off than at the 1% cut-off.

Factors influencing interobserver reproducibility

There was significant association between interobserver reproducibility and specimen type (Table 3). The ICC for TPS was significantly higher in the resection group (0.926 ± 0.050) than in the EBUS-TBNA group (0.887 ± 0.099). The κ coefficient for the 3-step assessment was significantly higher in the biopsy group (0.776 ± 0.104) than in the EBUS-TBNA group (0.669 ± 0.089).

| Table 1. Intraclass correlation coefficient of the tumor proportion score |
|-----------------------------|------------------------|-----------------------------|
|                            | ICC for TPS            | p-value                     | Weighted Kappa for 3 tiered assessment | p-value |
| Total (n=26)                | 0.902 ± 0.058          | 0.091 ± 0.034               | 0.748 ± 0.093                           | 0.037  |
| Expert (n=19)               | 0.919 ± 0.034          | 0.859 ± 0.088               | 0.772 ± 0.073                           | 0.043  |
| Fellow (n=7)                | 0.859 ± 0.088          |                             | 0.680 ± 0.115                           |        |

ICC, Intraclass correlation coefficient; TPS, tumor proportion score.
The EBUS-TBNA group showed almost perfect agreement for the 50% cut-off, but fair agreement for the 1% cut-off. ICCs for TPS were influenced by histologic subtype (Table 4). The squamous cell carcinoma group showed higher agreement than the adenocarcinoma group. There was no significant difference between κ coefficients for the 3-step assessment.

There was significant association between interobserver reproducibility and experience (formal PD-L1 training, more experience for PD-L1 test, and longer practice duration on surgical pathology). The ICC for TPS was significantly higher in the trained group (0.922 ± 0.034) than in the untrained group (0.709 ± 0.101). There was low linear correlation between ICC for TPS and experience for PD-L1 assessment (Spearman correlation coefficient = 0.422) (Table 6). There was no correlation between the κ coefficient for the 3-step assessment and experience for PD-L1 assessment. The ICC for TPS was significantly higher in the expert group (91.9% ± 3.4%) than in the fellow group (85.9% ± 8.8%) (Table 1). The κ coefficient for the 3-step assessment was also significantly higher in the expert group (0.772 ± 0.073) than in the fellow group (0.680 ± 0.115). The κ coefficient for the 3-step assessment was significantly different in biopsy specimens between the expert group (0.807 ± 0.034) and the fellow group (0.693 ± 0.129) (p = 0.0013). In EBUS-TBNA and resection specimens, the κ coefficient of the expert group was slightly higher than that of the fellow group but there was no statistically significant difference between the two groups. There were no differences in κ coefficients at 1% and 50% cut-offs between the expert group and fellow group (Table 2).

**DISCUSSION**

We investigated the interobserver reproducibility of assessment of PD-L1 expression in NSCLC and observed good interobserver agreement for PD-L1 scoring. Pathologists were highly concordant for TPS with an ICC of 0.902. Rimm et al.8 examined the interobserver reproducibility for 22C3, 28-8, SP142, and E1L3N PD-L1 assays. Ninety samples were assessed by 13 pathologists. ICC was 0.882 for the 22C3 assay. The ICCs for 28-8, SP142, and E1L3N assays were 0.832, 0.869, and 0.859, respectively, showing high concordance. The findings suggest that PD-L1 assay is a reliable method for assessing PD-L1 expression in tumor cells.

We report good interobserver agreement for 1% and 50% cut-offs with κ coefficients of 0.633 and 0.834, respectively (Table 7). Cooper et al.9 investigated the interobserver reproducibility for

EBUS-TBNA, Endobronchial ultrasound-guided transbronchial needle aspiration; ICC, intraclass correlation coefficient; TPS, tumor proportion score.
assessment of the 22C3 PD-L1 assay. Two separate sample sets of 60 samples each were designed for the 1% and 50% cut-offs that contained equally distributed PD-L1 positive and negative samples. The sample set for the 1% cut-off contained 10 positive samples close to the cut-off, and the sample set for the 50% cut-off contained 20 negative or positive samples close to the cut-off. Ten pathologists assessed a sample set of 108 samples obtained after pooling the 1% cut-off and the 50% cut-off sample sets together. The \( \kappa \) coefficient was 0.68 for the 1% cut-off and 0.58 for the 50% cut-off. Brunnström et al. examined interobserver reproducibility for the 28-8, 22C3, SP142, and SP263 assays. Seven pathologists assessed 55 samples. For the 22C3 assay, 2%–20% of cases were differently classified by any one pathologist compared to the consensus at the 1% cut-off, and 0%–2% of the cases were differently classified by any one pathologist compared to the consensus at the 50% cut-off. For all four assays, there were 0%–20% and 0%–5% differently classified cases at 1% and 50% cut-offs, respectively. Variation in the number of differently classified cases by any one pathologist compared to the consensus was statistically significant between cut-offs. The number of differently classified cases was significantly lower for the SP142 assay compared to that for the other three assays. This difference was probably because there were many obviously negative cases for SP142. Rimm et al. reported that \( \kappa \) coefficients for the mean of all 4 assays were 0.537 and 0.749 at 1% and 50% cut-offs, respectively. Interobserver concordance for the PD-L1 assay was higher at the 50% cut-off than at the 1% cut-off, except for the results of Cooper et al. It is possible that Cooper et al. used sample sets to artificially enrich with samples close to the cut-offs, which is not possible in clinical practice.

The interobserver concordance for TPS and the 3-step assessment correlated with practice duration and was higher in the expert group than in the fellow group. This is probably because pulmonary pathologists were familiar with the varied morphologies of cancer and cancer-associated immune cells and had experience assessing other immunohistochemistry biomarkers, such as anaplastic lymphoma kinase, human epidermal growth factor receptor 2, and estrogen receptor. There was no difference in concordance between the expert group and fellow group for 1% and 50% cut-offs, similar to the results of Brunnström et al. Experience in conducting the PD-L1 test impacted interobserver concordance for TPS but not for 3-step assessment. These analyses suggested that the currently used 1% and 50% cut-offs are relatively reliable regardless of pathologist experience.

Our study reported that 1-day training improved interobserver reproducibility, whereas 1-hour training had no or very little impact on interobserver reproducibility. Therefore, 1-day training may be more effective than 1-hour training.

Tumor histologic subtype and specimen type influenced interobserver reproducibility, which was not previously reported. EBUS-TBNA showed lower interobserver agreement than resection and biopsy specimens at the 1% cut-off. Although squamous cell carcinoma showed higher agreement for TPS than adenocarcinoma, no significant difference was observed for the 3-step assessment. Strong membranous staining of macrophages, non-specific cytoplasmic staining of tumor cells, weak and/or partial membranous staining of tumors cells, heterogeneous staining intensities, and patchy staining are well-known interpretation pitfalls in assessing any PD-L1 assay.8-10 While using the 1% cut-off, misinterpretation of very few or even single cells may lead to false positive or false negative results. Training and an external quality assessment program should be organized with special focus on difficult cases and on assessing the 1% cut-off. Guidelines including examples and strategies for difficult cases should be developed.

The limitations of our study include the lack of a “true gold standard” and outcome data for therapy. However, gold standard assessment was undertaken by highly trained experienced specialists. The following were strengths of the present study: it is more representative of real clinical practice than previous studies.

For the mean of all four assay (22C3, 28-8, SP142, and E1L3N); bDifferently classified cases by any one pathologist compared with consensus.

8-10
whole sections from many samples were used to evaluate the reproducibility of PD-L1 assays, more observers than previous studies, and participating pathologists worked in different centers and had different levels of experience.

In conclusion, our results indicate that PD-L1 staining provides a reliable basis for decisions regarding anti-PD-1 therapy in NSCLC. Although interobserver agreement for the 1% cut-off was relatively lower, it was substantial and acceptable. Better training, longer assay experience, and an external quality assessment program could improve interobserver reproducibility for the 1% cut-off.

MicroRNA-374a Expression as a Prognostic Biomarker in Lung Adenocarcinoma

Yeseul Kim, Jongmin Sim,1 Hyunsung Kim, Seong Sik Bang, Seungyn Jee, Sungeon Park, Kiseok Jang

Department of Pathology, Hanyang University College of Medicine, Seoul; †Department of Pathology, Samsung Medical Center, Seoul, Korea

Background: Lung cancer is the most common cause of cancer-related death, and adenocarcinoma is the most common histologic subtype. Lung cancer is the most common cause of cancer-related death, and adenocarcinoma is the most common histologic subtype. MicroRNA (miRNA) is a single-stranded, non-coding regulatory RNA of 19–25 nucleotides in length. miRNAs are one of the components of the RNA-induced silencing complex that inhibits target gene expression either by causing mRNA degradation or suppressing mRNA translation. As miRNAs can bind mRNA by incomplete complementarity of sequences, a single miRNA can regulate multiple target genes. Previous miRNA expression profiling studies of various human malignancies have identified potential biomarkers for early diagnosis, classification, prognosis, and therapeutic response. MicroRNA-374a (miR-374a) has been investigated due to its involvement in the carcinogenesis and tumor progression of solid tumors and hematologic malignancies. Previous studies demonstrated that miR-374a promotes cell proliferation and metastasis of osteosarcoma, hepatocellular carcinoma, pancreatic cancer, breast cancer, and esophageal cancer by targeting various tumor suppressors, including Axin2, MIG-6, SRCIN1, LACTB, and ARRB1. However, some studies demonstrated the tumor suppressive role of miR-374a in colon cancer, T-cell lymphoblastic lymphoma, and non-small cell lung cancer (NSCLC) by targeting cyclin D1, PTEN, and AKT.

In this study, miR-374a expression was measured using the quantitative real-time polymerase chain reaction (qRT-PCR) technique with RNA extracted from formalin-fixed, paraffin-embedded (FFPE) tumor tissues of 111 lung adenocarcinoma samples. The expression of miR-374a was correlated with clinical and clinicopathological parameters, including clinical stage T category (chi-square test, p = .004) and pleural invasion (chi-square test, p = .034). Survival analysis revealed that patients with high miR-374a expression had significantly shorter disease-free survival relative to those with low miR-374a expression (log-rank test, p = .032).

Conclusions: miR-374a expression may serve as a potential prognostic biomarker for predicting recurrence in early stage lung adenocarcinoma after curative surgery.

ventional clinicopathologic parameters as well as patient survival.

MATERIALS AND METHODS

Patients and tumor samples

A total of 184 consecutive cases of curative surgery for primary lung adenocarcinoma conducted at Hanyang University Hospital, Seoul, Korea, from 2003 to 2014 were retrospectively selected. Of the total 184 cases, 37 (20.1%) were excluded due to the lack of a suitable FFPE sample and 36 of the remaining patients were excluded because of the poor quality of FFPE RNAs. Finally, qRT-PCR for miR-374a and the U6 control was successful in 111 cases and further statistical analyses were performed. None of the patients received preoperative therapy. Clinicopathological data were collected and reviewed from the medical records and histopathological reports, and additional review of archived pathologic slides was conducted. The clinicopathological parameters included patient age, sex, tumor size, T category, pleural invasion, lymph node metastasis, American Joint Committee on Cancer (AJCC) tumor stage, histological grade, lymphovascular invasion, and perineural invasion. Histologic grading was determined by conventional histological criteria, including architectural abnormalities and cytologic atypia. Most cases with histologic grade 1 were categorized as lepidic predominant subtype, cases with grade 2 were categorized as acinar or papillary predominant subtype, and cases with grade 3 were categorized as solid or micropapillary predominant subtype based on the new 2015 World Health Organization classification. Disease-free survival (DFS) was measured from the date of operation until recurrence or death. Overall survival (OS) was measured from the date of operation until the time of death or the last follow-up.

RNA extraction and qRT-PCR

To identify areas most representative of tumors and non-necrotic tumor sections, we reviewed and marked histologic slides. Three or four 10-µm-thick tissue sections from each block were collected. Total RNA was isolated from the FFPE tumor tissues using miRNeasy FFPE kits (Qiagen, Hilden, Germany) according to the manufacturer's instruction. The concentration and purity of extracted RNA was measured using a NanoDrop 2000 spectrophotometer (NanoDrop Technologies, Waltham, MA, USA).

Universal cDNA synthesis kits (Exiqon, Vedbaek, Denmark) were used to convert RNA into cDNA. qRT-PCR experiments were performed with a mixture of diluted cDNA samples, an miR-374a specific primer set (Exiqon), and an ExiLENT SYBR Green Master mix (Exiqon). PCR was performed using a CFX96 thermocycler (Bio-Rad, Hercules, CA, USA) under the following conditions: 95°C for 15 minutes followed by 45 cycles of 95°C for 10 seconds and 60°C for 1 minute. After PCR amplification, melting curve analysis was performed to confirm the specificity of PCR products. The expression level of miR-374a was calculated using the 2-ΔCt method relative to the U6 small nuclear RNA (RNU6B).

Statistical analysis

Statistical analysis was performed using SPSS ver. 21.0 software (IBM Corp., Armonk, NY, USA). Chi-square tests were used to evaluate associations between miR-374a expression and various clinicopathological parameters of pulmonary adenocarcinoma patients. Kaplan-Meier survival curves for both DFS and OS were plotted, and the log-rank test was applied to establish the level of significance. The Cox proportional hazard regression model was employed in both univariable and multivariable survival analyses. A p-value of <.05 was defined as statistically significant.

Ethics statement

This study was approved by the Institutional Review Board (IRB) of Hanyang University Hospital (IRB file no. 2016-07-038) with a waiver of informed consent.

RESULTS

Clinicopathological characteristics of patients enrolled in the study

Two-thirds of patients were over 60 years of age (n = 68, 61.3%) and more females than men (n = 65, 58.6%) were included in the study. Most of the cases were categorized as histologic grade 2 (n = 78, 69.6%) and AJCC stage I (n = 76, 68.5%). Lymph node metastasis was found in 25 cases (22.5%), pleural invasion in 46 cases (41.4%), lymphovascular invasion in 40 cases (36.0%), and perineural invasion in 21 cases (18.9%). The clinicopathological characteristics are summarized in Table 1.

Correlations between miR-374a expression and clinicopathological characteristics in pulmonary adenocarcinoma

The quantitative measures of relative miR-374a expression in all 111 lung adenocarcinoma samples were as follows: mean, 0.048; median, 0.066; standard deviation, 1.585; and range, 0.000–11.794. The patients were divided into two groups (low
vs high) according to the median value of miR-374a expression. We analyzed the associations between miR-374a expression and clinicopathological characteristics, including age, sex, AJCC stage group, primary tumor (T category), lymph node metastasis, pleural invasion, histologic grade, lymphovascular invasion, and perineural invasion. High miR-374a expression was correlated with advanced T category (chi-square test, p = .004) and the presence of pleural invasion (chi-square test, p = .034) (Table 2).

**Prognostic value of miR-374a expression in pulmonary adenocarcinoma**

The median follow-up interval of patients for OS and DFS was 27.3 months (range, 0.9 to 118.6 months) and 25.7 months (range, 0.9 to 85.0 months), respectively. Local recurrence or metastasis was found in 18 patients, and 9 patients died during the follow-up period. On univariate survival analysis, AJCC stage, T category, lymph node metastasis, histologic grade, lymphovascular invasion, and perineural invasion were revealed as prognostic factors for DFS and/or OS (Table 3). Patients with high miR-374a expression showed shorter DFS compared to those with low miR-374a expression, and the difference was statistically significant (log-rank test, p = .032) (Fig. 1). However, miR-374a expression level was not an independent prognostic factor in multivariable survival analysis. The OS of the patients with high miR-374a expression was also inferior to those with low expression; however, the difference failed to demonstrate a statistical significance. In addition, stage-stratified survival analyses revealed that high miR-374a expression was significantly associated with shorter DFS only in patients with AJCC stage I (log-rank test, p = .006).

**DISCUSSION**

Fresh frozen tissue has been mostly used for high-throughput miRNA expression profiling for human cancers. However, sampling and long-term storage of fresh tumor tissue is laborious and expensive in daily clinical practice. As tumor specimens are routinely stored as FFPE blocks after diagnostic process in pathology archives and can be linked with medical records, emerging interest has been directed toward whether FFPE tissue can be used for studies of miRNA biomarkers. Interestingly, miRNAs appear to be stable in FFPE samples, even exhibiting near total mRNA degradation. Preservation of miRNA in FFPE tumor samples has been confirmed in previous studies, and the results obtained from qRT-PCR analyses, miRNA expression profiling, and even next-generation sequencing studies are consistent with those of fresh frozen tissue. These results suggest that quantifying miRNA expression level using FFPE tissue can enable the identification of clinically-available miRNA biomarkers in human malignancies.

One of the clinical significances of measuring miRNA expression level in resected tumor tissues is to identify patients at high risk of recurrence or cancer-related death after curative surgery. Zheng et al. reported that NSCLC patients with low miR-195 expression showed poor overall survival. In the study of Chen et al., low miRNA-148a expression was significantly correlated with high histologic grade, frequent lymph node metastasis, and a poor OS in NSCLC. Further, miR-21, as an oncogenic miRNA, has been reported as a biomarker for predicting recur-
rence, metastasis, and resistance of radiation and chemotherapy in NSCLC. In our study, high miR-374a expression correlated with advanced pT category, pleural invasion, and poor DFS in lung adenocarcinoma. Zhao et al. investigated miR-374a expression level in 158 NSCLC tissues by in situ hybridization. They found that miR-374a was highly expressed in NSCLC relative to non-neoplastic tissues and correlated with lymph node metastasis and poor clinical outcome. However, in the study of 38 Estonian NSCLC cases (18 squamous cell carcinomas and 20 adenocarcinomas), low miR-374a expression, as by miRNA Table 2. microarray, was associated with poor survival. This discrepancy may result from the difference in miRNA detection methods and study population, such as ethnicity and histologic type. Lack of reproducibility between studies suggests that further validation with a larger case series and optimization of detection methods is needed for clarification.

Most previous studies have reported miR-374a as an oncogenic miRNA in various cancer types. In studies with osteosarcoma cell lines, tumor cells transiently transfected with miR-374a mimic showed an increase in cell proliferation and colony formation by downregulating FOXO1 and/or Axin2. Downregulation of miR-374a inhibited cell proliferation, migration, and invasion in breast cancer cell lines (MDA-MB-23a and MCF-7) by targeting LACTB. In triple-negative breast cancer, ARRB1 was a direct target of miR-374a, and knockdown of miR-374a attenuated cell proliferation and migration in vitro.

![Fig. 1. Kaplan-Meier survival curves of lung adenocarcinoma patients stratified based on miR-374a expression level.](image-url)
regulation of miR-374a inhibited tumor growth and decreased Ki-67 proliferation index in xenograft mice. However, some studies have reported miR-374a as a tumor suppressive miRNA. Induced overexpression of miR-374a in colon cancer cell lines inhibited cell proliferation and invasion based on in vitro assays and a xenograft model by targeting cyclin D1. Nasopharyngeal cancer cells transfected with miR-374a mimic inhibited cell proliferation and invasion in vitro, and showed a decreased number of metastatic lesions in a mouse model. These results suggest that miR-374a may have dual roles in tumor progression, and the role depends on the major target pathway in a given cancer subtype.

In conclusion, our data show that high miR-374a expression correlates with advanced pT category and pleural invasion. High expression of miR-374a may serve as a potential prognostic biomarker for predicting recurrence in early stage lung adenocarcinoma after curative surgery. Further validation studies for a prognostic biomarker and related mechanism should be explored.

7. Zhang J, He Y, Yu Y, et al. Upregulation of miR-374a promotes tumor metastasis and progression by downregulating LACTB and pre-

Gastrointestinal stromal tumors (GISTs) are the most frequent mesenchymal neoplasms of the gastrointestinal (GI) tract, with an incidence reported at 10–15 per million persons. GISTs can be found anywhere within the GI tract, most commonly in the stomach (55.6%) and small intestine (31.8%).

The cell of origin and diagnostic criteria were highly debated until 1998, when it was confirmed that GISTs can be found anywhere within the GI tract, most commonly in the stomach (55.6%) and small intestine (31.8%). The cell of origin and diagnostic criteria were highly debated until 1998.3-5

GISTs have a wide morphological spectrum, and although spindle cell tumors are the most common, 20%–25% of GIST cases present an epithelioid pattern, and some cases show mixed histology. Currently, diagnosis is based on morphology, ancillary tests including immunohistochemistry (95% express CD117 and 98% express DOG1), and molecular profiling.6-10 Among clinicopathological features, the most universally applicable prognostic factors for GISTs are tumor size and mitotic rate per 50 high power fields (HPF).1,7,8

Nearly 80% of GISTs harbor a mutation in KIT, and another 5%–10% of cases have platelet-derived growth factor receptor (PDGFR) mutation.9 However, approximately 10%–15% of GISTs have no mutation in either of these genes and were previously known as wild-type GISTs.6 However, the terminology “wild-type GISTs” is progressively being abandoned as mutations have been identified in BRAF and succinate dehydrogenase (SDH) genes.9,10 In tumors with a KIT mutation, the most commonly affected region is exon 11 (juxtamembrane domain; 70%), followed by exon 9 (extracellular domain; 10%–15%), exon 13 (tyrosine kinase 1 domain; 1%–2%), and exon 17 (activation loop; 1%).11-14 Secondary mutations in exons 13, 14, or 17 are usually present in imatinib-resistant patients.15

Management of GIST patients is currently based not only on clinicopathological features (e.g., risk assessment and tumor stage), but also genetic changes including KIT-, PDGFR-A-, and SDH mutations.8 To our knowledge, however, the detailed characteristics and molecular genetic features of GISTs have not yet been
described in the Vietnamese population.

In this study, we conducted a standard clinicopathological risk assessment and evaluated the relationships between expression of Ki-67 and p53 and the clinicopathological features of GISTs in Vietnamese patients. Furthermore, we investigated the common regions of KIT mutation, comprising exon 11, exon 9, exon 13, and exon 17.

MATERIALS AND METHODS

Tissue samples

In a descriptive study design, 155 primary GISTs were collected from patients who underwent surgical resection between 2011 and 2014 at the University Medical Center at Ho Chi Minh City (Ho Chi Minh City, Vietnam). Patients treated with preoperative imatinib were not enrolled in the study. The diagnosis was confirmed based on the histological features and immunoreactivity of CD117.

Clinicopathological data of age, sex, tumor location, tumor size, and tumor stage were recorded. Localized GISTs were those that were confined to the primary organ of origin, and locally advanced GISTs were those with contiguous organ involvement. Morphological features, such as pattern (spindle cell, epithelioid, or mixed) and mitotic activity (per 50 HPFs with a total area of 5 mm²) were evaluated. For risk assessment, tumors were categorized into very low-, low-, intermediate-, and high-risk groups based on the National Institute of Health (NIH) classification.16

For immunohistochemical analysis, we used archival formalin-fixed, paraffin-embedded (FFPE) tissues from the 155 GISTs. One or two representative tumor blocks from each case were examined using immunohistochemistry.

For KIT genotyping, 100 FFPE tissues were available for KIT mutation analysis. Genomic DNA was isolated from paraffin-embedded tissues and tested at KIT exons 9, 11, 13, and 17.

Immunohistochemistry

Three-micrometer-thick slides were used for immunohistochemical analysis. Primary antibodies for CD117 (1:400, polyclonal, Ventana, Oro Valley, AZ, USA), Ki-67 (1:25, MIB-1 monoclonal, Dako, Carpinteria, CA, USA), p53 (1:50, DO-7 monoclonal, Dako), smooth muscle actin (SMA; 1:2,000, 1A4, monoclonal, Dako), and neuron-specific enolase (NSE; 1:50, VI-H14, Dako) were used to detect protein expression. Immunostaining for CD117, Ki-67, p53, SMA, and NSE was performed using an automated staining machine (VENTANA BenchMark, Ventana) according to the manufacturer’s instructions. For the markers (CD117, SMA, and NSE), immunostaining was defined as positive if ≥ 10% of tumor cells were stained and negative if < 10% of tumor cells were stained. The labeling index (LI) (%) for Ki-67 and p53 expression was evaluated based on a count of at least 1,000 tumor cells in the highest-density immunoreactivity areas of the positive tumor nuclei. Ki-67 and p53 were defined as positive if the LI was higher than 10%17 or 5%,18 respectively. Two senior surgical pathologists without knowledge of the clinicopathological features of the patients independently reviewed the immunostaining slides. Intenobserver differences were resolved by consensus review using a double-headed microscope after independent review.

KIT genotyping

Genomic DNA was extracted from paraffin-embedded tissues of 100 patients using the ReliaPrep FFPE gDNA Mini-prep System kit (Promega, Madison, WI, USA) according to the manufacturer’s protocol. Amplifications of KIT exons 9, 11, 13, and 17 were performed using Takara Taq HotStart Polymerase (Takara Bio, Shiga, Japan) with primers as previously published.19 Polymerase chain reaction (PCR) fragments were sequenced and analyzed in both sense and antisense directions using a BigDye Terminator v3.1 kit on an ABI 3130 Genetic Analyzer (Applied Biosystems, Foster City, CA, USA). Mutations were confirmed through a second independent PCR amplification and sequencing.

Statistical analysis

Associations between clinicopathological features and Ki-67 expression, p53 expression, and KIT mutations were analyzed using the chi-square test and Fisher’s exact test. Differences were considered significant at p < .05. All statistical analyses were performed using SPSS software ver. 16.0 (SPSS Inc., IBM, Chicago, IL, USA).

Ethics statement

This study was approved by the Board of Ethics in Biomedical Research at the University of Medicine and Pharmacy at Ho Chi Minh City, Vietnam (approval number: 54/UMP-BOARD; Date: December 22, 2012). Informed consent was obtained from all individual participants included in the study.
RESULTS

Clinicopathological characteristics of GISTs

We included 72 (46.5%) male and 83 (53.5%) female patients in this study, with a male: female ratio of 1:1.2, and the median age at diagnosis was 55 years (range, 15 to 88 years). Tumor size ranged from 1.0 to 29 cm in the largest dimension, with a median size of 6 cm. The GISTs presented in a wide distribution both within and outside the GI tract (Table 1). The most common location was the stomach (52.3%), followed by the jejunum-ileum (27.7%). GISTs were also found outside the GI tract including the omentum (5.8%) and retroperitoneum (3.2%).

Most cases showed spindle cell (72.3%) or epithelioid cell morphology (14.8%), and mixed type accounted for 12.9% of cases (Table 1, Fig. 1A–C). Tumor cells were positive for CD117 (Fig. 1D). Many GISTs were positive for SMA (20%) (Fig. 1E) or for NSE (67.7%) (Fig. 1F). Sixty-seven of 155 cases (43.2%) were classified as high risk, 42 (27.1%) as low risk, 40 (25.8%) as intermediate risk, and 6 (3.9%) as very low risk (Supplementary Table S1). Most tumors located in the jejunum-ileum (55.8%) or the colorectum (44.4%) fell into the high-risk category (Table 2). Of the 14 cases of extra-intestinal GISTs, 13 (92.9%) were classified as the high-risk group.

We next evaluated Ki-67 and p53 expression in the GISTs (Fig. 1G, H). Of the 155 cases, 52 (33.5%) were positive for Ki-67, and 58 (37.4%) were positive for p53 (Table 1). Expression of Ki-67 correlated with mitotic rate (p < .001), tumor size (p = .014), risk assessment (p < .001), and tumor stage (p < .001) (Table 3). Similarly, expression of p53 correlated with mitotic rate (p < .001), tumor risk assessment (p < .001), and tumor stage (p < .001). In contrast, expression of Ki-67 and p53 was not associated with GIST phenotype (p = .482 and p = .102, respectively).

KIT mutation analysis

KIT mutations were detected in 68 of 100 GIST cases (68%). Sixty-two of the 68 KIT mutations (91.2%) were found in KIT exon 11 (Table 4). There were two cases (2.9%) with mutations in KIT exon 9 and 4 cases (5.8%) with mutations in KIT exon 17. No mutations were found in KIT exon 13. We detected a variety of KIT mutation types in exons 9, 11, and 17 including point mutations, insertions, deletions, duplications, and complex mutations.

Among the cases with mutations in KIT exon 11, in-frame deletion was the most common type (35/62, 56.5%) (Fig. 2A), followed by point mutation (19/62, 30.6%) (Fig. 2B). Complex mutations were detected in six of 62 cases (9.7%). The two cases with mutation in the extracellular membrane region encoded by exon 9 were insertions (Y503_F504insAY) (Fig. 2C) and were found in tumors of the jejunum-ileum. All mutations in KIT exon 17 were point mutations, and three of four cases (75%) had an N822K substitution (Fig. 2D). We further investigated the relationships between KIT mutation status and other clinicopathological characteristics; however, no significant correlation was found (Supplementary Table S2).

DISCUSSION

A systematic review of 29 studies on nearly 14,000 GIST patients reported a median age of 60 years, and the incidence was similar for males and females.2 Our study showed a slightly higher incidence rate in females and a median age lower than in other studies. However, our average age was higher than that of the Korean sub-population reported in the systemic review mentioned above.2 Although many studies have reported the presence of GISTs in the esophagus,12 no esophageal GISTs were present in our study. Our results showed that GISTs were most predominant in the stomach, followed by the small intestine, which was consistent with the findings in most of the literature. Interestingly, our results revealed that extra-intestinal GISTs accounted for 9% of cases. According to a study in Singapore from

GISTs, gastrointestinal stromal tumors; SMA, smooth muscle actin; NSE, neuron-specific enolase.
1998 to 2008, the frequency of extra-intestinal GISTs has increased since CD117 immunohistochemistry has been applied for diagnosis.20

According to the literature, most GISTs have high-risk features, followed by intermediate- and low-risk groups.2,17,18,20,21 Our study also had a majority of GISTs classified as high-risk, followed by low-risk, intermediate-, and very low-risk groups. Our study revealed that most jejunum-ileum and colorectal GISTs fell into the high-risk group. These results were compatible with a previous study in which non-gastric GISTs were mostly classified in the high-risk group.22 Our study showed an extremely high ratio of extra-intestinal GISTs in the high-risk group. In contrast, another study with 29 extra-intestinal GIST cases showed seven cases (24.1%) in the high-risk group using the criteria of mitotic rate per 50 high power fields ≥ 5/50 HPF and Ki-67 ≥ 10%.23 Recently reported evidence proposed that retroperitoneal GISTs could be derived from a GI tract origin.24

In our study, Ki-67 expression correlated with risk assessment and other clinicopathological features, as in previous studies.17,18,25,26 Although the cut-off value for Ki-67 expression varied among studies, it is clear that Ki-67 expression is a prognostic factor and a good marker for biological behavior such as metastatic tendency.17,18,25,26 Furthermore, TP53, the most mutated gene in human cancer,27 has also been proposed to be a predictive

Values are presented as number (%). GISTs, gastrointestinal stromal tumors.
The marker for risk of malignancy in GISTs.\textsuperscript{17,28} The cut-off value for p53 expression varied among studies.\textsuperscript{17,18,28} One study from Japan that used the same cut-off values for p53 expression and risk assessment as our study showed less frequent p53 expression in the high-risk group.\textsuperscript{18} However, in our study, there was a significant correlation between p53 expression and high-risk assessment.

Pauser et al.\textsuperscript{28} reported that expression of p53 was related to epithelioid morphology. However, our study showed that p53 expression was not correlated with the morphologic phenotypes of GISTs.

In the current study, \textit{KIT} mutations were found in 60\%--80\% of GISTs and were most frequently detected in exon 11, which is consistent with previous reports.\textsuperscript{1,4,6,29,30} Additionally, \textit{KIT} mutations were not associated with the clinicopathological features of GISTs. According to the National Comprehensive Cancer Network (NCCN) panel, the presence and type of \textit{KIT} mutation are not strongly correlated with prognosis.\textsuperscript{8} However, another study showed that GISTs with \textit{KIT} exon 11 deletions and high mitotic rates were negatively correlated with recurrence-free survival.\textsuperscript{31} In the American College of Surgeons Oncology Group (ACOSOG) Z9001 trial, GIST patients with \textit{KIT} exon 11 deletion mutations had longer recurrence-free survival than those with other mutation types (genotypes) when treated with adjuvant imatinib.\textsuperscript{32}

Interestingly, the second most frequent region of \textit{KIT} mutation in this study was exon 17. Two of four cases with \textit{KIT} exon 17 mutations were identified in the stomach. Other studies have reported that primary mutations in \textit{KIT} exon 17 were fre-
quently detected in tumors of the small intestine,\textsuperscript{11,33} and approximately 1% of newly diagnosed GISTs had detectable mutations in \textit{KIT} exon 17.\textsuperscript{11} Furthermore, \textit{KIT} exon 17 mutations as a secondary mutation (including N822K substitution) were often found in cases with acquired imatinib resistance.\textsuperscript{34,35} Our study did not detect any mutations in \textit{KIT} exon 13, and mutations in \textit{KIT} exon 9 were only identified in two cases. According to the NCCN guidelines, patients with advanced GISTs with \textit{KIT} exon 9 mutations who are treated with double the standard dose of imatinib have an improved likelihood of response.\textsuperscript{8}

Our study has several limitations. Because it is a descriptive study, it lacks clinical outcome information for the patients, which would enable us to determine overall and disease-free survival. Furthermore, additional analysis to investigate the status of \textit{PDGF}-\textit{FRA} and \textit{SDH} mutations in the “wild-type” GIST cases (32\%) to reveal a more comprehensive picture of the molecular alterations in Vietnamese GIST patients would be helpful but was not feasible at this point.

In conclusion, this study demonstrated the clinicopathological features, immunohistochemical characteristics, and \textit{KIT} mutation status of 155 Vietnamese GIST patients. The stomach was the most common site of GISTs, followed by the small intestine, outside the GI tract, and colorectum. The majority of GISTS outside the GI tract fell into the high-risk group. Expression of Ki-67 and p53 was associated with high-risk assessment. Mutations in \textit{KIT} exon 11 were the most frequently detected, followed by mutations in \textit{KIT} exons 17 and 9. However, \textit{KIT} mutations were not associated with clinicopathological or morphological features.

REFERENCES

Risk factors for squamous cell carcinoma of the tongue (SCCOT) are well known and include a history of smoking and alcohol consumption. Most incidences occur in older men; however, several reports indicate that the global incidence of SCCOT in young, non-smoking women has been rising, a trend also observed in the Korean population. A study by Choi et al. also found that the incidence of SCCOT in younger patients, particularly women, has been increasing. SCCOT in young patients presents with similar clinical outcomes to those for older patients. Distinct epidemiological features are apparent for these two cohorts, such as weaker association with smoking and drinking in younger patients, suggesting that biology and pathogenesis in these groups might also be distinct.

This study was designated to compare a set of clinicopathological parameters between sexes (male and female) and age groups (young and old). Young was defined as adults under 45; no standard definition of young regarding SCCOT has been established; however, a cutoff of 45 is frequently used in related studies. Expression levels of several proteins were also compared through immunohistochemical (IHC) staining. Targeted proteins include p16, p53, mdm2, cyclin D1, and glutathione S-transferase P1 (GSTP1), all of which were associated with tumorigenesis of SCCOT in previous studies. p16, p53, mdm2, and cyclin D1 are essential to regulation of the cell cycle and apoptosis. Abnormal expression of these proteins in oral squamous cell carcinoma (SCC) has frequently been reported, implying an association with the pathogenesis and prognosis of SCCOT. Some reports have shown that expression levels vary by age groups. GSTP1 is a member of the glutathione S-transferase enzyme superfamily that participates in detoxification processes. Exposure to toxic substances such as tobacco, alcohol, and betel is a major risk factor for SCCOT, and impaired GSTP1 function has been associated with an increased cancer risk.

The increasing proportion of women under 45 years old with SCCOT suggests potential involvement with sexual hormone receptors, and increased ER expression in SCCOT has been reported for oral SCC. Recent studies found a relationship be-
between oropharyngeal SCC and hormone receptor expression.\textsuperscript{22,23} We performed IHC stains for ER, progesterone receptor (PR), and androgen receptor (AR) to evaluate previous results and further analyze other clinicopathological features associated with hormone receptor expression.

\section*{MATERIALS AND METHODS}

\subsection*{Study population}

After searching an anonymized research database at Asan Medical Center, 295 cases of histologically confirmed SCCOT were found from 2005 to 2012. Ninety-six cases were excluded due to the lack of an available tissue block or clinical data, and 189 cases were finally retrieved for this retrospective study.

\subsection*{Clinical data collection}

Clinical parameters collected from electronic medical records included age at onset, sex, smoking status, alcohol consumption level, treatment history, recurrence, and survival. Patients under 45 years old were classified as young patients. Smoking status was classified as non- or ex-smoker (no smoking for at least 1 year), or current smoker. Smokers were further categorized into light (< 1 pack of cigarettes/day) and heavy smokers (≥ 1 pack of cigarettes/day). Drinkers with a history of more than seven drinks per week were considered heavy drinkers. A drink was defined as roughly 14 g of pure alcohol regardless of beverage type, equivalent to approximately 12 ounces of regular beer. Cutoff values of heavy smoking and drinking were set by as described in previous work\textsuperscript{24-26} wherein patients over these cutoff values showed a significantly increased risk of oral epithelial dysplasia or cancer. Disease-free survival (DFS) was calculated from the date of initial pathological diagnosis to the date of radiological or clinical recurrence, while overall survival (OS) was calculated to the date of patient death.

\subsection*{Pathological review and tissue microarray construction}

All available hematoxylin and eosin slides were reviewed to obtain pathological parameters, such as tumor size, histologic grade, depth of invasion (DOI), stromal tumor-infiltrating lymphocytes (TIL) group, lymphovascular invasion (LVI), perineural invasion (PNI), and TNM stage. TNM stage for each case was revised based on the American Joint Committee on Cancer (AJCC), 8th edition.\textsuperscript{27} TIL assessment criteria followed the International Immuno-Oncology Biomarker Working Group guidelines.\textsuperscript{28,29} Each tumor was assigned to low, intermediate, or high TIL group according to the percentage of stromal area occupied by lymphocytic infiltrate (low, < 20%; intermediate, 20%–50%; high, > 50%). For the construction of tissue microarray (TMA) blocks, two tissue cores of approximately 2 mm were excised from the central area of the SCCOT and from tumor margins with normal mucosa.

\subsection*{Immunohistochemistry}

IHC staining for p16 (1:6, clone E6H4, mouse mAb, Ventana Medical Systems, Tucson, AZ, USA), p53 (1:1,500, clone M7001, mouse mAb, Dako, Glostrup, Denmark), ER (1:200, clone 6F11, mouse mAb, Novocastra, Newcastle upon Tyne, UK), PR (1:200, clone 16, mouse mAb, Novocastra), AR (1:100, clone SP107, rabbit mAb, Cell Marque, Rocklin, CA, USA), mdm2 (1:50, clone SMP14, mouse mAb, Zeta, Arcadia, CA, USA), cyclin D1 (1:100, clone SP4, mouse mAb, Cell Marque), and GSTP1 (1:6,000, mouse mAb, Cell Signaling, Danvers, MA, USA) was conducted in accordance with the manufacturer’s manual on a Ventana BenchMark XT Autostainer (Ventana Medical Systems). Serially cut 4-μm sections of the TMA block were deparaffinized, and antigen retrieval was carried out with EDTA buffer (cell conditioner #1) for 32 minutes (p16, p53, PR, AR, cyclin D1, and GSTP1) or 64 minutes (mdm2 and ER). After inactivation of endogenous peroxidase and rinsing with Tris buffer (reaction buffer), diluted primary antibodies were added and incubated for 16 minutes (p16, p53, PR, AR, cyclin D1, and GSTP1) or 32 minutes (mdm2 and ER) at 37°C. Expression levels of p53, p16, mdm2, and cyclin D1 were analyzed by a semiquantitative score based on the proportion of stained area (%) using criteria outlined in Table 1 and in reference to previous reports.\textsuperscript{19,30,31} GSTP1 was interpreted as weak or strong by cytoplasmic staining intensity. IHC stains for ER,
PR, and AR were considered as positive when nuclear expression was noted regardless of cellular proportion.

Statistical analysis
Statistical analysis was performed using SPSS ver. 25.0 (IBM Corp., Armonk, NY, USA). Results for age, tumor size, and DOI were described with mean and 95% confidence interval. The Mann-Whitney U test was used to compare tumor size and DOI between age and sex groups. The Kruskal-Wallis test was used for comparisons among the four groups (young men, young women, old men, and old women). Other clinicopathological parameters and IHC results were compared using Pearson’s chi-square test and the Fisher’s exact test. OS and DFS were analyzed according to the Kaplan-Meier method with univariate analysis (log-rank test). All calculated p-values were 2-sided, and values less than 0.05 were considered statistically significant.

Ethics statement
All procedures performed for the current study were approved by the Institutional Review Board (IRB) of Asan Medical Center (approval No. 2018-0395) in accordance with the 1964 Helsinki declaration and its later amendments. Formal written informed consent was waived by the IRB.

RESULTS
Patients were divided into four groups according to age and sex; young men, young women, old men, and old women. Clinical characteristics are listed in Table 2, and histopathological data are listed in Table 3. We also compared patients between age and sex groups. Clinicopathological data therein are included in the Supplementary Materials (Supplementary Tables S1–4).

Age at diagnosis ranged from 20.7 to 88.0 years (median, 56.1 years; 95% confidence interval, 52.88 to 57.26). Young patients accounted for 27.0% (51/189). Smoking and drinking status were markedly different between sexes, but not age groups (Tables 2, Supplementary Tables S1, 2). Most smokers (61/69, 88.4%) and regular drinkers (86/99, 86.9%) were men. Proportions of heavy smokers and drinkers were slightly lower in young patients, but these differences were not statistically significant. Women comprised 40.2% (72 of 189) of all patients. More women were in the young patient group (25 of 51, 49%), and more likely to be young non- or ex-smokers (21 of 30, 70%). OS and DFS were not significantly different by age (young or old) or sex (Fig. 1). Young women presented with relatively lower mortality rates (28.0%) than the other groups combined (48.2%), but this difference was not statistically significant (p=.082). Relatively poor survival among young men (50.0% vs 44.8% of others) was also observed but not statistically significant (p=.678).

Histologic grade tended to be higher in young patients (p=.021) but did not vary between sexes (Supplementary Tables S3, 4). When we compared the four groups divided by sex and age, none of the histopathological parameters including tumor size, DOI, and IHC results were significantly different (Table 3).

Values are presented as number (%) unless otherwise indicated. Cl, confidence interval.
DOI, histologic grade, LVI, PNI, TIL group, T and N category were significantly different for any group (Table 3). Notably, higher TIL was correlated to better OS (p=.002) and DFS (p=.017) rates (Fig. 2).

IHC stains for sex hormone receptors were positive in a small number of patients. Only a single case presented with nuclear expression of ER (51.1-year-old male, non-smoker) and two cases presented with expression of AR (case 1, 40.2-year-old female, non-smoker; case 2, 56.7-year-old, male, non-smoker). PR was not expressed in any of the study participant samples. Expression levels as determined by IHC stainings of p16, p53, mdm2, GSTP1, and cyclin D1 were compared between patients grouped by age, sex, and smoking and drinking status, and no significant differences were found for any cohort (Table 4). Among immunomarkers, cyclin D1 expression was correlated to OS (p=.009) and DFS (p=.011) (Fig. 3). Other markers (p53, mdm2, p16, and GSTP1) were not correlated to any clinicopathological parameters.

### Discussion

SCCOT in young and non-smoking patients has been reported since the 1980s but became a substantial issue after 2000 when epidemiologic evidence demonstrated an increasing incidence in this group. Previously, physicians thought that young SCCOT patients had poorer prognoses, and more aggressive treatments were used in this population. However, this notion has yet to be empirically substantiated.7 Many studies attempted to find biological factors unique to young patients with SCCOT, but distinctive features were not found.11,32,33 Indeed, SCCOT in young and old patients has not been found to exhibit relevant difference at the molecular level.34 Pickering et al.10 found certain genomic similarities between SCCOT in young patients and older smokers by whole-exome sequencing. However, these studies were mainly conducted by Western countries so data from Asian populations are insufficient. Recently, Sun et al.35 reported that prognoses for young Chinese patients with oral SCC were similar to those for...
Comparison of Tongue Cancer between Ages

373

older patients. In this study, we also found equivalent results for old and young patients from Korea.

Briefly, the only clinicopathological parameter that differed between young and old patients was histological grade (Table 3), which was found to be worse in the young group. Male-to-female ratios were also not statistically different by age, although a relatively higher proportion of women was observed in young patients. This tendency became more significant in the young, non-smoking group where women were predominant (21 of 27, 77.8%). This finding recapitulated those from previous studies reporting that young women with no history of tobacco or alcohol use were more vulnerable to SCCOT than their male counterparts.4 This epidemiologic peculiarity aroused our interest in a potential relationship between SCCOT and sex hormone receptor expression.

Previous studies reported ER expression in 11% to 50% of SCCOT cases.13,14,36 In this study, however, we only observed focal ER expression in a single patient, despite the use of automated IHC staining with a well-established primary antibody and staining protocol. The only ER-expressing tumor found was that of an older male with no history of smoking. Interestingly, in other reports, most patients presenting with ER-positive head and neck cancer were also older males.13,14 These results suggest that ER involvement might be primarily related to the original patient group of older men. PR was negative in all cases; this is also consistent with a previous report.14 Immunoreactivity with nuclear expression for AR was seen in two cases, in contrast to previous reports reporting AR positivity in up to 67% of patients, most of them expressing AR in the cytoplasm.37 Since true positivity for AR requires nuclear expression, the importance of AR expression in young SCCOT patients seems to be limited.

Inter-individual variation in metabolic capacity for toxins could influence the carcinogenesis of SCCOT in young patients. GSTP1 is an important detoxifying enzyme, but a relationship between GSTP1 and oral carcinogenesis remains unclear. Genetic polymorphisms in the GSTP1 gene has been reported to be associated with impaired metabolism of carcinogens, thereby elevating the risk of several tumors, including head and neck cancer.21,38 Soares et al.17 observed increased GSTP1 expression in non-tumor margins in both smoking and drinking patients and suggested that this result could be a reaction to carcinogen exposure. In the current study, all tumors presented with diffuse GSTP1 expres-

Fig. 1. Kaplan-Meier estimation of overall survival and disease-free survival curves for age and sex. Neither overall survival (A–C) nor disease-free survival (D–F) was significantly associated with age or sex.
Fig. 2. Examples of tumor-infiltrating lymphocyte (TIL) scores and Kaplan-Meier survival curves. Each tumor was given a TIL group depending upon the amount of stromal lymphocytic infiltration. Images represents low (A), intermediate (B), and high (C) group. Higher TIL groups were associated with better overall survival (D) and disease-free survival (E).

Comparison of Tongue Cancer between Ages

Overall intensity scores did not vary by age, sex or smoking or drinking status. We also found that strong GSTP1 expression was not related to prognosis. Epithelial tissues in non-tumor margins showed similar or slightly weaker intensities than those of matched tumor cells. These results suggest that expression of GSTP1 is not a suitable marker for individual cancer susceptibility or toxin exposure related to SCCOT.

Other IHC markers, p53, cyclin D1, mdm2, and p16, were variably positive in a significant proportion of cases but their expression levels were not statistically different by age, sex or smoking or drinking status. Strong expression of cyclin D1 was associated with poor prognosis, a finding that is consistent with previous reports. However, the lack of standardized interpretation criteria of cyclin D1 expression parameters compromises the reliability and integrity of these results. The relationship between cyclin D1 and SCCOT is worthy of further investigation, particularly with respect to standardizing the interpretation criteria. No standardized TIL assessment guideline for oral SCC exists, either. Several reports suggest a prognostic impact of TIL on oral SCC but they used different assessment methods and demonstrated conflicting results. We applied the TIL assessment method used in breast cancer and found a significant correlation between TIL and OS, implying that this method might be a candidate for standardized assessment.

This study evaluated the clinicopathological parameters and expression profiles of several tumorigenic candidate proteins of SCCOT and found no significant difference between young and old patients nor between male and female patients. Despite epidemiologic idiosyncrasy, SCCOT in young women appears to be similar to that in older men. Previous studies reported similar data and came to similar conclusions. These results, combined with epidemiological data, suggest the presence of unknown carcinogenic factors contributing to an emerging incidence of SCCOT in young women via a similar pathogenetic sequence to that associated with known risk factors. We investigated two candidates for these factors, hormone receptors and GSTP1, but significant findings were not observed. Considering that known risk factors are primarily associated with toxin exposure (tobacco, betel quid, or alcohol), extrinsic factors appear to be more important than individual factors of age, sex, or intrinsic metabolic activity in the pathogenesis of SCCOT. Possible exposure to toxic materials associated with altered lifestyles or new environmental pollutants should thereby be investigated in the young female SCCOT population.

REFERENCES

The follicular variant of papillary thyroid carcinoma (FVPTC) is the second most common type of papillary thyroid carcinoma (PTC) and accounts for 5%–41% of all PTC subtypes.1-4 FVPTC comprises two major subtypes: infiltrative FVPTC and encapsulated FVPTC (EFVPTC).1 The incidence of EFVPTC has gradually increased over the past two decades and constitutes more than 10% of all thyroid malignances diagnosed in North America and Europe.5 EFVPTC can be further classified into two subtypes: invasive EFVPTC and non-invasive EFVPTC based on the status of capsular or vascular tumor invasion.7 The majority of non-invasive EFVPTCs behave as indolent non-malignant tumors and have been renamed as non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) in Korea.
neoplasm with papillary-like nuclear features (NIFTP). This introduction of NIFTP concept has significantly affected clinical practice by reducing the therapeutic intensity for patients with EFVPTCs.

Differentiating NIFTP from invasive EFVPTC solely based on cytomorphologic findings is impossible when using thyroid fine needle aspiration cytology. NIFTPs are mostly interpreted as indeterminate categories. The two most common genetic mutations found in thyroid tumors are BRAF and RAS point mutations. RAS mutations occur in 30%–40% of EFVPTCs. The BRAFV600E mutation is absent in NIFTPs but can occur in up to 30% of invasive EFVPTCs.

In Korea, a low rate of NIFTP has been reported in several studies. However, the studies were limited by small sample size and single institution, and the results might not represent the general population. Therefore, in the present study, the prevalence of NIFTP among Korean patients was evaluated by reviewing multicenter-based data using the largest cohort size to date in Korea.

MATERIALS AND METHODS

Study cohort

Data from 18,819 patients with PTC from eight university hospitals were retrospectively analyzed. The tumors were diagnosed from surgically resected specimens between January 2012 and February 2018. The slides of all cases initially diagnosed as EFVPTC on pathology reports were reviewed and reclassified into NIFTP, invasive EFVPTC, and other PTC subtypes. The NIFTP was diagnosed according to the criteria of World Health Organization (WHO) Classification of Tumours of Endocrine and recently revised diagnostic criteria: (1) encapsulation or clear demarcation of the tumors (thick, thin, or partial capsule, or well circumscribed with a clear demarcation from adjacent thyroid tissues), (2) follicular growth pattern with no papillae (including microfollicular, normofollicular, or macrofollicular architecture with abundant colloid) with no psammoma bodies and < 30% solid/trabecular/insular growth pattern, (3) nuclear score 2–3, (4) no capsular or vascular invasion (requires adequate microscopic examination of the tumor capsule interface), (5) no tumor necrosis, (6) no high mitotic activity (high mitotic activity defined as at least 3 mitoses per 10 high-power fields (400×) (Fig. 1). A nuclear score of 2–3 is diagnostic of NIFTP. However, if florid nuclear features (nuclear score 3) of PTC are present, a meticulous histopathologic examination of the entire tumor is required for the detection of any true papillae, psammoma bodies, aggressive histology, or invasion into tumor capsule or vessels.

Molecular analysis of NRAS and HRAS genes

Molecular analysis of 27 NIFTP cases obtained from a single institution was performed. Genomic DNA was extracted from paraffin-embedded thyroid specimen blocks. The representative slides were selected and the tumor tissues were manually dissected under a stereomicroscope and stored in a 1.5 mL tube. Genomic DNAs were extracted from 5–10-µm-thick tissue sections using the QIAamp DNA Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions. Exon 3 of NRAS and HRAS genes was amplified using polymerase chain reaction (PCR) with the following primers: (1) NRAS-exon 3–197 bp, forward (5’-CCCCCTAACCCTCCACACC-3’) and reverse (5’-GAGGTTATATCCGCAAATGACTT-3’); (2) HRAS-exon 3–201 bp, forward (5’-GTCCTCCTGCGAGGATTCATA-3’) and reverse (5’-CGGCGGTCACCTGACTT-3’). The PCR cycling conditions for NRAS and HRAS mutations were as follows: initial activation at 94°C for 15 minutes; 35 cycles at 94°C for 30 seconds, 51°C–57°C for 30 seconds, 72°C for 30 seconds, final extension at 72°C for 10 minutes. The amplicons were analyzed using 2% agarose gel electrophoresis and purified using QIAquick PCR purification kit (Qiagen). The amplified PCR products were sequenced using Sanger sequencing. The amplicons were evaluated on 2% agarose gel electrophoresis and purified using the QIAquick PCR purification kit (Qiagen). The amplified PCR products were analyzed using the automated sequencing machine ABI 3730 (Applied Biosystems, Foster City, CA, USA), which performed Sanger sequencing using the same PCR primers.

Molecular analysis of KRAS gene

For detection of the KRAS mutation, a PNA Clamp KRAS mutation detection kit (Panagen, Daejeon, Korea) was used. The following reagents were used in all PCR reactions (total volume, 20 µL): 10 ng template DNA, primer, peptide nucleic acid (PNA) probe set, and SYBR Green PCR Master Mix. A CFX 96 (Bio-Rad, Hercules, CA, USA) was used for the real-time PCR of PNA-mediated clamping. PCR cycling conditions consisted of the following sequential steps: 5-minute hold at 94°C followed by 40 cycles at 94°C for 30 seconds, 70°C for 20 seconds, 63°C for 30 seconds, and 72°C for 30 seconds. All seven mutations in the KRAS gene were detected using one-step PNA-mediated real-time PCR clamping. PNA probes and DNA primers were used for the corresponding clamping reaction. SYBR Green flu-
orescent dye was applied for the detection of positive reaction signals. The amplification of the wild-type target was suppressed by the PNA probe sequence complementary to wild-type DNA. Due to this suppression, the amplification of mutant sequences was specifically preferred by competitive inhibition of DNA primers binding to wild-type DNA. The threshold cycle (Ct) value was used to evaluate PCR efficiency. The SYBR Green amplification plots were generated to analyze Ct values for the control and mutation assays. Mutation status was determined by Ct value differences ≥ 2, which were obtained between the control and samples.

**Molecular analysis of BRAF gene**

Mutational analysis of BRAF was performed using two different methods. The PNAClamp BRAF mutation detection kit (Panagene) was used to detect the BRAF<sup>V600E</sup> mutation. Each reaction tube had a total volume of 20 µL and included a mixture of template DNA, primers, PNA probe, and SYBR Green PCR Master Mix. Real-time PCR of PNA-clamping PCR was performed using a CFX96 real-time PCR system (Bio-Rad, Pleasanton, CA, USA). The PNA probe was complementary to wild-type (V600). PCR was performed under the following conditions: 5-minute hold at 94°C, 40 cycles of 30 seconds at 94°C, 20 seconds at 70°C, 30 seconds at 63°C, and 30 seconds at 72°C.
The PNA probe and primers incorporated in the assay were separate oligonucleotides, and the PNA probe location was placed between forward and reverse primers within the template. Interca
tion of SYBR Green fluorescent dye was used to detect positive signals.

Pyrosequencing for the \textit{BRAF} mutation analysis was performed as described in detailed elsewhere.\textsuperscript{21} The primers used for PCR were the following: forward primer (5'-GAAGACCTCA-CAGTTAAAAATAG-3') and reverse primer (5'-biotin-ATAGCCT-CAATTTCAATCC-3'). The pyrosequencing reaction was performed with a sequencing primer (5'-biotin-ATAGCCT-CAATTTCAATCC-3') on a Pyromark Q24 instrument (Qiagen). The PyroMark Q24 software (Qiagen) was used for analysis of the pyrogram results.

\textbf{Statistical analysis}
Clinicalopathological parameters of NIFTP before and after NIFTP introduction were analyzed using the chi-square test or Fisher’s exact test for categorical variables and the t-test for continuous variables. All statistical analyses were performed using SPSS ver. 22.0 (IBM Corp., Armonk, NY, USA). A \textit{p}-value of < 0.05 was considered statistically significant.

\textbf{Ethics statement}
The current study was approved by the Institutional Review Boards (IRBs) of eight institutions. Ethics approval for all procedures performed in the current study was obtained from the IRB (approval No. 3-2018-0271). Formal written informed consent was waived by the IRB.

\section*{RESULTS}

\subsection*{The prevalence of NIFTP in PTC cases}
To evaluate the incidence of NIFTP in the Korean population, data were retrospectively collected from the eight university hospitals in Korea. The incidence of NIFTP in each institution is shown in Table 1. After reviewing pathology reports of 18,819 patients with PTC, 378 patients (2.0\%) were initially diagnosed with non-invasive EFVPTC as potential NIFTP cases; 140 cases were excluded from NIFTP diagnosis after review of pathology slides acquired from 378 cases. The most common reason for exclusion was the presence of small, but true papillae that were reclassified as conventional PTC. Other reasons for exclusion were reclassification as infiltrative FVPTC or unavailability for slide review. Finally, 238 (1.3\%) of all PTCs were eligible for the diagnosis of NIFTP after slide review.

Among 238 cases of NIFTP, 174 cases (73.3\%) had only NIFTP; in the remaining 64 cases (26.7\%), NIFTP coexisted with other malignancies, such as conventional PTC, infiltrative FVPTC, tall cell variant PTC, oncocytic variant PTC, follicular carcinoma, or poorly differentiated carcinoma (Table 2).

Because not all cases were available for slide review and NIFTP can be misclassified as non-PTC tumors, the lower boundary for the prevalence of NIFTP among PTCs was estimated. When the same histologic criteria was applied for the diagnosis of NIFTP regardless of the tumor size, the prevalence of NIFTP was 238 (1.3\%) among all PTCs. Among the reclassified 238 NIFTP cases, 86 had a tumor < 1.0 cm and 152 had a tumor \geq 1.0 cm (Table 2). Therefore, the expected lower boundary for the prevalence of NIFTP was 0.8\% (152/18,819) when tumors \geq 1.0 cm were included for the diagnosis of NIFTP.

\subsection*{Clinicopathologic characteristics of patients with NIFTP}
Among 152 patients with NIFTP \geq 1.0 cm in size, 125 (82.2\%) patients had only NIFTP and the remaining 27 patients (17.8\%) had NIFTP coexisting with thyroid cancer. The clinicopathologic characteristics were evaluated in patients with only NIFTP. The demographics of 125 NIFTP patients are shown in Table 3. The mean age was 46.7 years (range, 23 to 73 years). The NIF-

\end{tabular}
\caption{Prevalence of NIFTP according to the tumor size among 18,819 patients with initial diagnosis of papillary thyroid carcinoma}
\end{tighttable}
TP patients included 93 females (74.4%) and 32 males (25.6%). The median primary tumor size was 26.2 mm (range, 10 to 80 mm). Among 125 patients, 101 (80.8%) underwent cervical lymph node dissection and lymph node metastasis was not found. In addition, no patient had lymphatic/vascular invasion or distant metastases. Regarding surgical methods, a total of 44 patients (35.2%) underwent total thyroidectomy and 81 patients (64.8%) received lobectomy or isthmectomy. Furthermore, 29 patients (23.2%) underwent radioactive iodine (RAI) remnant ablation therapy based on the initial tumor size. Disease recurrence was not observed in any NIFTP patient during a median follow-up period of 25.1 months.

### Impact of NIFTP on pathologic examination and clinical practice

A difference in the prevalence of NIFTP before and after NIFTP introduction was not observed (Table 3). The number of paraffin blocks for diagnosis of NIFTP did not increase after the introduction of NIFTP (average 5.2 per tumor before April 2016 and average 5.5 per tumor after April 2016). The rate of lymph node dissection increased from 72.7% before April 2016 to 89.8% after April 2016. The rate of total thyroidectomy decreased from 43.9% before April 2016 to 25.4% after April 2016. The number of patients undergoing postoperative RAI therapy was significantly reduced from 25.8% before April 2016 to 20.3% after April 2016 (Table 3). RAI treatment was performed due to coexisting thyroid cancers in most cases.

</table>

Values are presented as number (%) unless otherwise indicated. NIFTP, non-invasive follicular thyroid neoplasm with papillary-like nuclear features; SD, standard deviation.
*Before April, 2016; †Includes pN0 and pNx stages.
**BRAF and RAS mutations in NIFTPs**

Twenty-seven patients diagnosed with NIFTP at the Gangnam Severance Hospital after April 2016 were randomly selected for gene analysis; BRAF\(^{V600E}\) mutation was not observed. As shown in Table 4, the overall frequency of three RAS gene mutations was 55.6% (15/27). The mutation rates of NRAS, HRAS, and KRAS were 22.2%, 22.2%, and 11.1%, respectively.

**DISCUSSION**

The overall prevalence of NIFTP was 1.3% (range, 0.4% to 2.6%) of all PTCs in the present study, which included the largest cohort size researched to date among the Korean population (Table 1). According to the recent study by Nikiforov et al., \(^8\) any masses < 1.0 cm were not included in the diagnosis of NIFTP. Moreover, in another recent NIFTP study, data on the sub-centimeter NIFTP were limited. \(^22\) Thus, the expected lower boundary for the prevalence of NIFTP was 0.8% when tumors ≥1 cm in size were included in the diagnosis of NIFTP.

*KRAS mutation was analyzed by PNAClamp KRAS mutation detection kit. The assay cannot identify specific mutation types.

These results are consistent with the findings from a previous study in which the mean prevalence of NIFTP was 1.5% (range, 0% to 4.7%) in nine institutions from six Asian countries, including Korea. \(^23\) The prevalence of NIFTP is constantly lower in Asian studies than in Western population-based studies. \(^21,24,27\) NIFTPs frequently have RAS mutations but no BRAF\(^{V600E}\) mutation. \(^11,14\) However, the BRAF\(^{V600E}\) mutation was found in some NIFTP cases in several studies immediately performed after the initial publication of NIFTP. \(^17,18,26,29\) Table 5 summarizes the results of BRAF mutation in NIFTP reported in previous studies from six Asian institutions. \(^17,18,26,31\) When the strict criterion of “0% papillae” was applied in the present study, no BRAF mutation was found in NIFTPs. In the present case series, a case of BRAF\(^{V600E}\)-positive tumor originally diagnosed as non-invasive EFVPTC was found. The pathology slides were re-examined after cutting deeper sections and a true papillary structure was found in a focal area. Therefore, the case was reclassified as encapsulated classic PTC with predominant follicular growth pattern. This finding reconfirms the strict diagnostic criteria for NIFTP are helpful for excluding true PTC. Because the diagnostic criteria for NIFTP have been updated, NIFTP should no longer include any follicular patterned tumors with well-formed papillae or high-risk gene mutations such as BRAF\(^{V600E}\), TERT promoter, or TP\(^53\). \(^20\)

The present study had several technical limitations. First, due to the retrospective multicenter-based nature of this study, interobserver variability in the diagnosis of NIFTP based on histology was not considered. Second, since only the cases diagnosed with PTC were included, the possibility that NIFTP was diagnosed as benign, such as nodular hyperplasia or follicular adenoma, may result in differences in actual prevalence. However, the prevalence of NIFTP did not change significantly even after the introduction of NIFTP. Third, although the overall study cohort size was relatively large, genetic analysis of BRAF and RAS mutations

NIFTP, noninvasive follicular thyroid neoplasm with papillary-like nuclear features; PTC, papillary thyroid carcinoma.
were performed in only a limited number of NIFTP cases. Neverthe-
less, the results were consistent with previous study results
showing NIFTP has no \textit{BRAF}^{V600E} mutation and frequent \textit{RAS}
mutations.8,15,20

The results from this study have shown the low prevalence of
NIFTP among PTCs in Korea using the largest number of cases
to date. Adverse outcomes were not experienced by any patient
with NIFTP during the follow-up period. The introduction of
NIFTP may have a small overall impact in Korean practice.

Microsatellites, also known as short tandem repeats, are repetitive sequences usually composed of one to six base pairs, repeating from 5 to 50 times and accounting for about 3% of the whole human genome. Due to this repeated structure, DNA sequence mismatches are likely to occur during DNA replication. Mismatch repair (MMR) is a DNA repair system that can correct the errors. Failure to correct these errors during DNA replication results in a variation in the length of the repeat region, which is called microsatellite instability (MSI). MSI has been identified in about 15%–20% of colorectal cancer (CRC) which may be sporadic (12%–14%) or Lynch syndrome-associated (1%–3%). In sporadic colorectal cases, the tumors are mainly caused by epigenetic silencing of the MLH1 gene promoter by acquired hypermethylation, which is in association with a high CpG island methylation phenotype. It accounts for approximately 70%–90% of CRC with MSI. In Lynch syndrome, the tumors with MSI are frequently caused by autosomal dominant germline mutations in the MMR genes.

Currently, it is becoming increasingly important to determine the MSI status in patients with CRC because MSI–high (MSI-H) CRC is often associated with Lynch syndrome and MMR deficient CRCs can clinically benefit from immune checkpoint inhibitors. The MSI status can be detected by immunohistochemistry (IHC) for MMR proteins or polymerase chain reaction (PCR)–based MSI tests, which are currently considered the gold standard method. However, this method requires normal tissues, and it is time-consuming and labor-intensive. Recently, next-generation sequencing (NGS) has been reported to successfully detect the MSI status. This can be done by either direct sequencing of the microsatellite loci or analysis of the total mutation burden or proportion of insertion/deletion mutations. However, NGS experiments are expensive and only available in
specialized laboratories.

In this study, we tested Idylla MSI assay in terms of its diagnostic performance, the minimum requirements for tumor purity, and turnaround time through the examination of the surgically resected samples or colonoscopic biopsy CRC samples, the MSI status of which were rigorously confirmed through either standard PCR fragment analysis or clinical NGS test.

MATERIALS AND METHODS

Sample selection

Formalin-fixed paraffin-embedded (FFPE) tumor tissues from 115 pathologically confirmed CRC patients who underwent surgical resection (n = 109) or colonoscopic biopsy (n = 3) at Asan Medical Center from 2010 to 2016 were used. All samples had MSI results that were confirmed by standard PCR analysis, NGS test, or both. We used five markers (BAT25, BAT26, D2S123, D5S346, and D17S250) recommended by the National Cancer Institute (NCI) for the standard PCR MSI analysis. Diagnosis of the MSI status through NGS was carried out as described previously.7 Hematoxylin and eosin–stained slides from FFPE were reviewed by two pathologists (M.L and J.K.) for tumor distribution and cellularity. The areas of the slide presenting the highest tumor cellularity were marked, and tumor cellularity was evaluated by rough estimation of the proportion of tumor cell nuclei relative to non-neoplastic cell nuclei. In order to determine the minimum required tumor purity, the tumor area was marked in various ways so that various proportions of tumor nuclei could be included in the analytes in two cases.

Tissue handling was done according to the instructions provided by the manufacturers (Fig. 1). Briefly, macro-dissection was done if the tumor cellularity was less than 20%, and whole cut sections were used if it was more than 20% (Fig. 1). We obtained 5-µm FFPE tissue sections: 1 section when the tumor area is equal to or greater than 50 mm² and 2–5 sections when the tumor area is less than 50 mm² depending on the tumor surface area (Fig. 1). In most cases, macro-dissection was not required. The scraped FFPE tissue fragments were directly put into the cartridge.

The Idylla MSI assay

The Idylla MSI assay (Biocartis NV, Mechelen, Belgium) was performed as described previously.9 Briefly, the scraped FFPE tissue fragments were loaded directly onto a designated cartridge and the device was run for approximately 150 minutes. Detection of these specific targets was performed using fluorescently labeled molecular beacons after PCR amplification. These beacons melt differentially from the wild type or mutated amplicons with increasing temperature. The MSI test–specific software, namely, Test Type Package, automatically checked the validity of the measured fluorescence profiles: the presence of specific PCR amplicons resulted in biomarker-specific fluorescence profiles. Next, a powerful pattern-recognition specific algorithm trained on several thousands of profiles calculated a probability score (MSI score) for any given valid biomarker-specific profile. This MSI score per biomarker expressed the probability of a pattern being wild type or mutant. As such, MSI biomarkers were scored individually and reported as “No mutation detected,” “Mutation detected” or “Invalid.” The Idylla MSI assay uses seven biomarkers, namely ACVR2A, BTBD7, DIDO1, MRE11, RYR3, SEC31A, and SULF2. Those biomarkers were chosen based on their short length that is advantageous for probe-based PCR, stability over different cancer types and ethnicities, minimized false positives and negatives, and diagnostic performance optimized for the test platform. A test result was considered valid if ≥ 5 out of 7 MSI biomarkers show valid amplified signals. The tumors were classified into two categories. High frequency of MSI (MSI-H) was defined if two or more of the seven markers were positive, and microsatellite stable (MSS) if less than two of seven markers

---

Fig. 1. Sample processing protocol depending on the tumor purity and tissue surface area. FFPE, formalin-fixed paraffin-embedded.
were positive.

**Determination of limit of detection**

We randomly selected four cases that were confirmed as MSI-H by standard PCR analysis and determined the limit of detection through stepwise tumor marking that results in varying degrees of tumor cellularity. As shown in Supplementary Fig. S1, we designated the tumor areas with varying degrees of non-neoplastic cells so that the approximate tumor cellularity is 80%, 60%, 40%, 20%, or 10%, respectively. In three cases, samples with approximately 5% and/or 2% tumor purity were also analyzed (Supplementary Fig. S1).

**Statistical analysis**

We compared the results of Idylla MSI assay with the combined gold standard MSI results for the 105 cases. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of Idylla MSI assay were calculated for each test in comparison with the combined gold standard.

**Ethics statement**

Written informed consent was obtained from all patients and this study was approved by the Institutional Review Board (protocol number: 2018-1518).

**RESULTS**

**Idylla MSI assay**

All 115 cases showed “valid” results. Thirteen out of 115 cases (11.3%) were classified as MSI-H (Table 1). Mutations were detected in at least four of seven marker genes in these 13 MSI-H cases (Table 1). Among the MSS samples, most cases did not reveal any mutation in the seven markers; however, a particular case (case No. 71) showed MRE11 mutation on Idylla MSI assay but the assay categorized it as MSS because the probability score was below the threshold.

**Validation of the MSI status through standard PCR analysis, NGS, or both**

Standard PCR analysis for MSI using the five markers recommended by NCI were carried out in the 108 cases except for the seven cases that were not available for tissue analysis. Of the 108 cases, 89 cases were MSS, five cases were low frequency of MSI (MSI-L), and 14 cases were MSI-H. The NGS test for MSI was performed on all 115 cases, and three of them failed during the library preparation step of NGS analysis. Of the 112 cases with valid NGS results, 101 cases were MSS while 11 cases were MSI-H. The results of standard PCR analysis and the results of NGS test results for MSI were completely concordant in all 105 cases with both test results, except for the cases without available tissue material for standard PCR analysis and those that failed the NGS test (Table 2). We combined the results of standard PCR analysis and NGS test and thereafter used the combined results as a gold standard. For standard PCR results, MSI-L results were considered MSS.

**Comparison between Idylla MSI assay and the gold standard MSI results**

We compared the results of Idylla MSI assay with the combined gold standard MSI results for the 105 cases with both results of

Standard PCR analysis and NGS test. Idylla MSI assay achieved 99.05% accuracy (104 of 105), 100% sensitivity (11 of 11), 98.94% specificity (93 of 94), 91.67% positive predictive value (11 of 12), and 100% negative predictive value (93/93) for the detection of MSI (Table 3). Only one case (case No. 28) showed discordant result between the Idylla MSI assay and the gold standard result. MSS result was confirmed by both standard PCR fragment analysis (Fig. 2A) and NGS (Fig. 2C), but the Idylla MSI assay called it MSI-H.

Further evaluation of the cases that failed the NGS test

To investigate whether the Idylla MSI assay can accept a wider range of samples than NGS, we selected three cases that were confirmed as MSI-H in standard PCR test but failed in our NGS test. Among them, two cases showed instability on only two microsatellite markers (case Nos. 131 and 133) (Fig. 2D–H), while the other case (case No. 132) showed instability in all five markers (Table 4). Among them, only one case (case No. 132) showed concordant results and the other two showed discordant

Values are presented as number (%). MSI, microsatellite instability; MSS, microsatellite stable; MSI-H, MSI-high.

Fig. 2. Details of three cases with discrepant results between the Idylla microsatellite instability (MSI) assay and the standard polymerase chain reaction (PCR) test. (A–C) Case No. 28, MSI-high (MSI-H) according to the Idylla MSI assay. Standard PCR MSI test is consistent with microsatellite stable (MSS) (A). MSH2 and MLH1 expression is shown in immunochemical staining (B), and next-generation sequencing (NGS) results show MSS pattern (C). (D–F) Case No. 131, MSS (0/7) according to the Idylla MSI assay. Two markers show instability in standard PCR MSI test (arrows, D), and MSH6 and PMS2 protein expressions are shown (E). Repeated NGS shows MSS pattern (F). (G, H) Case No. 133, MSS (0/7) according to the Idylla MSI assay. Two markers show instability in standard PCR MSI test (arrows, G), and MSH6 and PMS2 expressions are shown (H). Repeated NGS analysis was failed. Mutation load, the number of total somatic mutations detected by our NGS panel; TMB, tumor mutation burden, the inferred number of somatic mutations per megabase; I index, the number of insertion or deletion mutations divided by the number of all mutations; IHC, immunohistochemistry.
results. Interestingly, the two cases with discordant results were the cases where instability was observed in two markers in the standard PCR analysis. To resolve these discrepancies, additional immunohistochemical staining for MSH2, MSH6, MLH1, and PMS2 were performed and standard PCR analysis and NGS was repeated. Although repeated PCR MSI tests were not helpful due to the high background noise band (data not shown), protein expression of all the MMR proteins was preserved in the two cases (Fig. 2B, E), suggesting that those two cases were likely MSS. Furthermore, the second attempt of NGS was successful in case No. 131 and it showed MSS pattern although the tumor mutation burden was relatively high (28.13/Mb) (Fig. 2F). The second attempt of NGS was not successful in case No. 133. As expected, the MSI-H phenotype of the case with concordant standard PCR and Idylla MSI results was confirmed through the loss of MSH2 and MSH6 expression (Table 4).

Limit of detection analysis of the Idylla MSI assay

To determine the minimum tumor purity that does not affect the assay results, we selected a few MSI-H samples and macro-dissected each sample in such a way that various levels of tumor purity could be achieved. Case No. 118 was successfully categorized as MSI-H when the tumor purity was lowered down to 10% (Table 5). Likewise, case Nos. 104 and 113 were successfully categorized as MSI-H even in samples with lower tumor purity of 2%. However, in case No. 52, which was diagnosed as MSI-H based on the presence of mutations in six out of seven markers, no single mutation was detected in all seven biomarkers when the tumor cellularity was 2%. In this particular case, there were several foci of lymphoid aggregates which may further dilute the tumor cells (Supplementary Fig. S1E).

DISCUSSION

In this study, the Idylla MSI assay demonstrated excellent diagnostic performance when we tested the fully automated kit with 115 CRC samples with rigorously confirmed MSI results. In addition, the test successfully detected MSI-H status in samples with very low tumor purity (down to 10%), although the tumor purity estimates were inevitably crude. Our findings suggest

that the Idylla MSI assay could be used in the clinic to determine MSI status, at least for CRC samples, and that macro-dissection may not be required in most CRC cases. Since the Idylla MSI assay does not require DNA extraction and reagent loading steps, the hands-on time could be greatly reduced.

The identification of MMR deficiency is important not only for the identification of the risk for Lynch syndrome but also for the appropriate treatment approach and prognosis for sporadic tumors. MMR deficiency can be diagnosed by PCR fragment analysis, NGS, and MMR protein IHC test. MMR IHC staining is used as a first-line screening method and is used as a good surrogate marker for MSI, but heterogeneity has previously been well described. PCR fragment analysis has been widely used as a standard method and NGS-based MSI detection is now increasing, but both methods are time-consuming and labor-intensive. The Idylla MSI assay offers a fully automated workflow from direct FFPE tissue input to a simple final report (Supplementary Fig. S2) and achieved a short turnaround time (about 150 minutes) and minimal hands-on time (less than 2 minutes). When we simulated actual hands-on time in maximum throughput environment (8 samples/run for the Idylla MSI assay, 32 samples/run for the standard MSI PCR assay, and 24 samples/run for the NGS in Illumina NextSeq platform), the hands-on time per sample was 30 seconds for the Idylla MSI assay, 5 minutes for the standard MSI PCR test, and 120 minutes for the NGS. Thus, the Idylla MSI assay may significantly save time and manpower.

The downside of the Idylla MSI assay, however, is that only one sample can be processed in each instrument unit at a time. Thus, to increase sample throughput, multiple instruments are required (up to 8 instruments per one console, according to the manufacturer). Requirements for multiple instruments and usage of one sophisticated cartridge per one sample may make this test to be more expensive than the standard PCR assay.

Although the Idylla MSI assay results were concordant with gold standard results in most cases, there was one false-positive case (case No. 28). The gold standard result was MSS but the Idylla MSI assay categorized it as MSI-H based on the presence of mutations in four genes such as ACVR2A, BTBD7, MRE11, and SULF2. Since the MSS result was confirmed by both standard PCR fragment analysis and NGS, it is unlikely that the gold standard result was incorrect. Furthermore, cross-contamination or sample swapping was rigorously excluded through repeated analysis and DNA fingerprinting that is included in our NGS assay. It could be that the particular tumor harbored somatic mutations in the four genes, irrespective of MMR deficiency. Indeed, one MSS tumor (case No. 71) showed MRE11 mutation on the Idylla MSI assay but the assay categorized it as MSS because the total probability score was below the threshold. Thus, rare false MSI-H results may be possible in a particular MSS tumor harboring mutations in the genes covered by the Idylla MSI assay.

Most molecular techniques involving homogenized samples, in which the tumor cells and non-neoplastic cells are mixed, require tumor marking with subsequent macro-dissection to ensure sufficient tumor purity. Regarding this, the direct use of unstained FFPE tissues cut without macro-dissection could maximize the benefits of the fully automated Idylla MSI assay. In this study, we found that most FFPE samples may not require macro-dissection because the test reliably detected MSI-H in samples with low tumor purity (approximately 10%). However, since the ability to detect MSI-H was not perfectly consistent with the very low tumor purity (approximately 2%), we propose that the minimum required tumor purity would be approximately 10%. In addition, the age of the FFPE tissue material may not cause any significant problem in most cases because the test was successful in FFPE samples aged up to 9 years.

We also tested whether the Idylla MSI assay might accept poor quality samples better than the NGS assay by testing samples that were diagnosed as MSI-H with the standard PCR test but failed in our NGS analysis. All the Idylla MSI assay results were "valid" which means successful amplification of the adequate number of marker genes, suggesting that the Idylla MSI assay may accept some "difficult" samples better than NGS. Furthermore, MMR protein IHC study and repeated NGS analysis suggested that the Idylla MSI assay may sometimes be more accurate than the standard PCR MSI test because the two samples, which were MSS on the Idylla MSI assay but were MSI-H on the standard PCR test, showed unequivocal expression of four MMR proteins and a relatively low number of unstable markers (only two unstable markers out of five markers) in the standard PCR MSI test. In addition, in one of the two samples, MSS could be confirmed through repeated NGS analysis. However, the full validation of the performances of the Idylla MSI assay might be limited because of a relatively small size of the MSI-H sample group in our study.

In summary, the Idylla MSI assay is fast, accurate, and reliable, and thus might be clinically applicable. The fully automated workflow may offer a significant reduction in time and labor although the cost for consumables or cartridge is higher than that of the standard MSI PCR test. In addition, colonoscopic biopsy specimens in the case of initially metastatic disease may be easily processed because this test does not require a matched
normal tissue sample.

Hyperchromatic crowded groups (HCGs) are defined as three-dimensional aggregates of crowded cells with hyperchromatic nuclei, and are frequently encountered in cervicovaginal liquid-based cytology (LBC). Here, we aimed to examine the prevalence of HCGs in cervicovaginal LBC and the cytomorphological characteristics of various epithelial cell clusters presenting as HCGs.

Methods:
We first examined the prevalence of HCGs in a “routine cohort” of LBC cytology (n = 331), consisting of all cervicovaginal LBCs accessioned over 3 days from outpatient clinics (n = 179) and the screening population (n = 152). Then we examined a second “high-grade epithelial cell abnormalities (H-ECA) cohort” (n = 69) of LBCs diagnosed as high-grade squamous intraepithelial lesion (HSIL), squamous cell carcinoma (SCC), or adenocarcinoma during 1 year.

Results:
HCGs was observed in 34.4% of the routine cohort and were significantly more frequent in the epithelial cell abnormality category compared to the non-neoplastic category (p = .003). The majority of HCGs represented atrophy (70%). Of the 69 histologically confirmed H-ECA cases, all contained HCGs. The majority of cases were HSIL (62%), followed by SCC (16%). Individually scattered neoplastic cells outside the HCGs were significantly more frequent in SCCs compared to glandular neoplasia (p = .002). Despite the obscuring thick nature of the HCGs, examining the edges and the different focal planes of the HCGs and the background were helpful in defining the nature of the HCGs.

Conclusions:
HCGs were frequently observed in cervicovaginal LBC and were mostly non-neoplastic; however, neoplastic HCGs were mostly high-grade lesions. Being aware of the cytomorphological features of different HCGs is important in order to avoid potential false-negative cytology interpretation.

Key Words: Hyperchromatic crowded groups; Cervical neoplasms; Liquid-based cytology

MATERIALS AND METHODS

Subjects
In order to examine the prevalence of HCG in everyday practice, we first reviewed all cervicovaginal LBC slides accessioned at Seoul National University Hospital during 3 days in January 2012 (“routine cohort”), including specimens from the outpatient clinics and from the screening population (health promo-
tion center). All LBC slides were prepared by the BD SurePath system (BD Diagnostics, Burlington, NC, USA).

We collected a second cohort (“high-grade epithelial cell abnormalities [H-ECA] cohort”) of all cervicovaginal LBC cases diagnosed as HSIL, squamous cell carcinoma, adenocarcinoma, or atypical glandular cell (AGC) from January 2012 to December 2012 at Seoul National University Hospital, in order to examine in more detail the cytomorphological characteristics of neoplastic HCGs. Among a total of 1,130 retrieved cases, we included only cases that were confirmed by histological examination (concurrent or subsequent biopsies or operative specimens), and we also excluded all conventional smears. The remaining 69 cases were subjected to detailed cytomorphological review and the patient age information was obtained from the pathology database.

Cytological review

All the cervicovaginal smears were reviewed by two pathologists (H.K. and Y.L.). The cytological details examined included the cytological diagnosis, presence of endocervical/transformation zone (EC/TZ) components, presence and the nature (neoplastic versus non-neoplastic) of HCGs, and the presence of scattered single neoplastic cells in the background. We defined HCGs as dense cellular aggregates of at least 10 cells and excluded HCGs consisting of neutrophil clusters and bacterial colonies.

Statistical analyses

Statistical analyses were performed using SPSS statistics ver. 25.0 (IBM Corp., Armonk, NY, USA). The student t-test, Pearson chi-square test, and Fisher exact test were used. A p-value of less than .05 was considered statistically significant.

Ethics statement

This study was approved by the Institutional Review Board of Seoul National University Hospital (#H-1905-090-1034) and informed consent was waived due to the retrospective nature of the study.

RESULTS

Prevalence of HCGs in routine cervicovaginal LBC

A total of 331 cases were collected in the routine cohort, of which 152 cases (45.9%) were from the screening population and the remaining 179 cases (54.1%) were from outpatient clinics. The cases consisted of eight cases (2.4%) and 323 cases (97.6%) in the ECA and negative for intraepithelial lesion or malignancy (NILM) categories, respectively (Fig. 1). The ECA cases of the routine cohort consisted of one squamous cell carcinoma, one adenocarcinoma, one AGC, one low-grade squamous intraepithelial lesion (LSIL), and four atypical squamous cells of uncertain significance (ASC-US). The AGC case was subsequently confirmed as endocervical adenocarcinoma by histology. In the routine cohort, HCGs were observed in 114 cases (34.4%). The frequency of HCGs was significantly higher in the ECA category (7/8, 87.5%) compared to the NILM category (107/323, 33.1%; p = .003).

The majority of HCGs in the NILM group comprised atrophic parabasal cell clusters (n = 75, 70.1%), and the remainder were endocervical or metaplastic cells (n = 25, 23.4%) and endometrial cells (n = 7, 6.5%). The HCGs in atrophy were characterized by flat monolayer sheets of parabasal cells with nuclear overlapping in individual focal planes. The constituent parabasal cells had dark nuclei and scant cytoplasm, but the nuclei showed regular nuclear contours and were frequently even, smudgy and degenerated (Fig. 2A). Maturation of parabasal cells at the edges of HCGs and the streaming pattern with preserved polarity were helpful clues in classifying the HCGs as atrophic.

Endocervical cells frequently presented as a large HCG fragments, and focusing up and down revealed the regular honeycomb arrangement with distinct cytoplasmic borders (Fig. 2B). Reactive endocervical cells often demonstrated prominent nucleoli, mild nuclear size variation and even occasional mitotic figures (Fig. 2C). However, the presence of a streaming pattern, smooth and round nuclear outlines and mild nuclear hyperchromasia were indicative of reactive cellular changes. Metaplastic HCGs showed dense cytoplasm and spindled cytoplasmic projections.

Fig. 1. Summary of the routine cervicovaginal liquid-based cytology (LBC) cases. Hyperchromatic crowded groups (HCGs) were significantly more frequent in the epithelial cell abnormality (ECA) category compared to the negative for intraepithelial lesion or malignancy (NILM) category, and neoplastic HCGs were high-grade lesions. LSIL, low-grade squamous intraepithelial lesion; AGC, atypical glandular cell; ASC-US, atypical squamous cells of uncertain significance. aSubsequently diagnosed as adenocarcinoma; bOnly non-neoplastic HCGs were observed.
Endometrial cells appeared as very dense cellular clusters, and although the centers of HCGs were too dark to appreciate the cytomorphology even by examining different focal planes, the biphasic gland-stroma pattern was a helpful feature for identifying the endometrial cells (Fig. 2D). The periphery of the HCGs were lined by glandular cells with high nuclear:cytoplasmic ratio and small, hyperchromatic nuclei.

In the ECA group, all HCGs in the squamous cell carcinoma and glandular lesions were neoplastic HCGs. However, all cases diagnosed as ASC-US (n = 4) demonstrated only non-neoplastic HCGs, and there were no HCGs in the LSIL case. All neoplastic HCGs were seen in the outpatient clinic setting, and were not seen in the general screening population.

As expected, the mean age of subjects with atrophic HCGs (62.8 ± 7.9 years) were significantly higher compared to those with endometrial HCGs (39.5 ± 4.8 years) in the NILM group (p < .001). Interestingly, EC/TZ components were present in all 114 HCG-positive cases, while 34 of 217 HCG-negative cases (15.7%) did not contain EC/TZ components (p < .001). On comparing the screening and outpatient populations, no statistically significant differences were seen in the age distribution or the frequency of HCGs.

**Prevalence and characteristics of neoplastic HCGs**

All 69 cases of the H-ECA cohort contained HCGs. The H-ECA cohort consisted of 63 uterine lesions (91.3%) (HSIL [n = 43], squamous cell carcinoma [n = 11], endometrial cancer [n = 7], endocervical cancer [n = 2]) and six extrauterine (8.7%) (ovarian [n = 4], colorectal [n = 2]) lesions (Fig. 3). The endometrial lesions comprised four endometrioid carcinomas, one clear cell carcinoma, one serous carcinoma, and one carcinosarcoma. All extrauterine lesions were adenocarcinomas.

All HCGs (100%) in the glandular neoplasia were neoplastic HCGs. In contrast, in the squamous lesions, neoplastic HCGs were observed in 45 cases (83.3%). Neoplastic HCGs were seen in all of the squamous cell carcinomas, while they were seen in 34
of HSILs (79.1%). The remaining nine (20.9%) HSILs showed individually scattered HSIL cells without neoplastic HCGs.

Neoplastic squamous HCGs (HSIL and squamous cell carcinoma) were characterized by neoplastic cells with anisocytosis, increased nuclear:cytoplasmic ratio, and hyperchromatic nuclei with coarse chromatin (Fig. 4A, B). Tumor diathesis was seen in squamous cell carcinomas, and the presence of scattered atypical dyskeratotic cells were helpful features in recognizing the HCG as squamous (Fig. 4C). Neoplastic endocervical glandular HCGs demonstrated acinar patterns within the HCGs and the neoplastic cells were often columnar cells with pseudostratification (Fig. 4D). Smaller sheets and strips of neoplastic cells were present outside the HCGs with more obvious rosette-like patterns (Fig. 4E). The tumor cells frequently demonstrated macronucleoli, and scattered single cells were observed in one endocervical adenocarcinoma case. When the squamous and glandular HCGs were compared, squamous HCGs tended to show flattening of cells at periphery of HCG and oval-to-round nuclei (Fig. 4A, B), while the glandular HCGs demonstrated acinar patterns within the HCGs and cigar-shaped nuclei (Fig. 4D). HCGs of endometrioid carcinomas were characterized by tight clusters of smaller neoplastic cells (Fig. 4F). The nuclear pleomorphism was subtle in the well-differentiated tumors, while more obvious

Fig. 3. Summary of the high-grade epithelial cell abnormalities cohort. The majority were squamous lesions (78%).

Fig. 4. Cytological features of neoplastic hyperchromatic crowded group (HCG). (A–C) HCGs of squamous cell carcinoma demonstrate dense cellular clusters with chaotic arrangement, and the individual cells are markedly hyperchromatic. The periphery of the HCG is flattened. When present, tumor diathesis and scattered dyskeratotic cells are helpful features in recognizing squamous cell carcinomas (C). (D, E) HCGs of endocervical adenocarcinomas. A vague acinar arrangement is seen within the HCG with feathering of the border (D). Smaller strips and rosettes of tumor cells are helpful clues in the diagnosis (E). (F) HCGs of well-differentiated endometrioid carcinoma were tight clusters of neoplastic cells that were smaller than endocervical adenocarcinoma. More obvious nuclear atypia were present in high-grade tumors and intracytoplasmic neutrophils were also present (inset).
nuclear atypia was present in high-grade endometrioid carcinomas. Intracytoplasmic neutrophils (“bags of polys”) were also seen in one case (Fig. 4F, inset). The ovarian and colorectal carcinoma cases all showed glandular cell clusters: the background of the ovarian cancer metastases were clean, while the two colorectal adenocarcinomas demonstrated a necrotic and inflammatory background, suggestive of direct invasion of the uterine cervix by the tumor.

When we examined the presence of individually scattered neoplastic cells in the background, invasive squamous cell carcinomas more frequently demonstrated neoplastic single cells compared to glandular neoplasia (10/11 vs 4/15, respectively; \( p = .002 \)). Glandular lesions demonstrating scattered neoplastic cells were all primary uterine lesions (3 endometrial carcinomas and 1 endocervical adenocarcinoma), and extraternate neoplasms all presented as cellular clusters on cervicovaginal cytology.

**DISCUSSION**

HCGs have received more attention in cervicovaginal cytology since the introduction of the LBC test, as the HCGs are more visible against the monolayer background with the LBC method, compared to conventional smears. As LBC is being increasingly used (in Korea, the proportion of cervicovaginal LBC tests has increased from 7.6% in 2004 to 25.3% in 2015), it is important to be aware that HCGs may occasionally be the causes of false-negative or false positive cytology interpretation and to become familiar with the morphological characteristics of different HCGs.

In this study, HCGs were observed in 34% of routine cervicovaginal LBC samples, although less than the previously reported literature. The majority of HCGs were non-neoplastic cell clusters as previously reported, and the non-neoplastic HCGs were mostly parabasal cell clusters in atrophy. However, the small number of neoplastic HCGs in this study were all high-grade lesions, suggesting that HCGs in cervicovaginal LBC should be carefully evaluated in order to avoid serious false-negative interpretations. Conversely, non-neoplastic HCGs may also be over-interpreted as abnormal; for example, specimens from the lower uterine segment have been reported to be over-diagnosed as positive in patients with histories of endocervical adenocarcinomas. Therefore, although the cytological evaluation of HCGs is often difficult due to the dense obscuring hyperchromasia of the clusters, it is still important to discriminate between neoplastic and non-neoplastic HCGs. One important tip is to evaluate the cytomorphology at the periphery of the HCGs, where the cells may be more spread out into a single layer. For example, we observed that atrophic cells are flattened at the edges of HCGs into monolayer sheets where the streaming pattern and the bland nuclear features are more easily appreciable. As another example, endocervical adenocarcinomas may show the typical feathery pattern of columnar cells at the edge of the HCGs. Secondly, it is useful to examine each focal plane of the HCG by focusing up and down. By examining each focal plane, it is possible to appreciate the lack of nuclear overlapping in atrophic cell clusters where the parabasal-like cells are stacked in multilayer sheets, and in the case of adenocarcinoma, vague acinar patterns may be visible within the HCGs. Finally, examining the scattered cells and the background outside the HCGs is extremely important. We found scattered neoplastic cells in the majority of squamous cell carcinomas in addition to the tumor diathesis. On the other hand, scattered neoplastic cells were relatively rare in glandular lesions; however, when present, the cytological features of the scattered cells showed the typical features of glandular neoplasia which helped the diagnosis.

In this study, all cases with HCGs in the routine cohort contained EC/TZ components, while about 15% of HCG-negative cases did not demonstrate EC/TZ components. The presence of EC/TZ components in LBC implies that the cervix has been properly sampled, and thus increasing the likelihood of detecting ECAs when present. Chivukula et al. reported that most HCGs were endocervical cell aggregates and that ECA was detected only when HCGs were present.

In efforts to solve the diagnostic dilemma of HCG, cell block preparations and immunohistochemistry for p16 have been studied on cases showing HCGs. These methods were particularly helpful in identifying neoplastic HCGs from menstrual contamination. An image analysis study of HCGs, where the area, shape and color intensity of HCGs were evaluated, demonstrated little discriminative value in defining the neoplastic or benign nature of HCGs.

To conclude, we examined the prevalence of HCGs in routine cervicovaginal LBC and described the morphological features of different types of HCGs. Examining the edges of HCGs, each plane of focus and scattered cells outside HCGs were helpful in the interpretation of the HCGs.

Anti–glomerular basement membrane (GBM) nephritis is characterized by circulating anti-GBM antibodies and crescentic glomerulonephritis (GN) with deposition of IgG along the GBM. In a limited number of cases, glomerular immune complexes have been identified in anti-GBM nephritis. A 38-year-old female presented azotemia, hematuria, and proteinuria without any pulmonary symptoms. A renal biopsy showed crescentic GN with linear IgG deposition along the GBM and mesangial IgA deposition. The patient was diagnosed as concurrent anti-GBM nephritis and IgA nephropathy. Therapies with pulse methylprednisolone and cyclophosphamide administration were effective. Concurrent cases of both anti-GBM nephritis and IgA nephropathy are rare among cases of anti-GBM diseases with deposition of immune complexes. This rare case of concurrent anti-GBM nephritis and IgA nephropathy with literature review is noteworthy.

Key Words: Anti-glomerular basement membrane disease; Immunoglobulin A; Crescentic glomerulonephritis
GN and IgA nephropathy, which was treated with intravenous methylprednisolone (500 mg/day for three successive days) with cyclophosphamide (500 mg/day) followed by oral prednisolone (50 mg/day). Plasmapheresis was avoided due to the possibility of side effects. Three months after the treatment, the anti-GBM antibody titer gradually decreased (anti-GBM titer, 15.6 U/mL) and renal function improved (Cr, 2.08 mg/dL) (Fig. 2).

This study was approved by the Institutional Review Board of Chungnam National University Hospital with a waiver of informed consent (IRB No. 2016-11-009) and performed in acor-

DISCUSSION

RPGN is classified into three categories as anti-GBM disease, immune complex disease, and ANCA-associated disease. Among these three categories, anti-GBM disease is the rarest and severest form of crescentic GN and is characterized by linear IgG deposition along the GBM with circulating anti-GBM antibodies. Overlapping features of crescentic GN are identified as coexistence of anti-GBM disease and ANCA antibodies, or anti-GBM disease and immune complex–mediated GN. ANCA antibodies are detected in 21% to 43% of anti-GBM disease patients and clinical characteristics of dual antibody–positive patients are documented. However, concurrent anti-GBM disease and immune complex–mediated GN is rarely reported and the most frequent form of combined immune complex GN is membranous nephropathy. Concurrent anti-GBM disease and IgA nephropathy is rare and clinical characteristics are not well understood.

Herein, a case of concurrent anti-GBM nephritis and IgA nephropathy is presented. A literature review for concurrent anti-GBM disease and IgA nephropathy using PubMed (http://www.ncbi.nlm.nih.gov/pubmed) was performed resulting in identification of a total of nine cases from nine articles between 1995 and 2016 (Table 1, Supplementary Table S1). The average age and sex of concurrent anti-GBM disease and IgA nephropathy in reported cases was 43 years old with a male:female ratio of 1:1.5. Cases were reported in China (n = 5), the United States (n = 2), Canada (n = 1), and Japan (n = 1). None of the cases was previously diagnosed as immune complex GN including IgA nephropathy. A recent history of hematuria or proteinuria was shown in 40% of cases and a history of upper respiratory tract infection was present in 20% of cases. None showed symptoms of hemoptysis or pulmonary involvement based on image analysis. Oliguria was seen in 10% of cases. The mean proteinuria, serum Cr levels, and anti-GBM antibody titer (among available cases) were 2.6 g/day, 5.0 mg/dL, and 180 EU/mL. The ANCA autoantibody was not identified. The percentage of fibrocellular or cellular crescents in renal biopsies was 59%. All cases were treated with steroids and some cases with combined cytotoxic immunosuppressive agents, including cyclophosphamide, mycophenolate mofetil, or methotrexate. Plasmapheresis was applied to 30% of cases. More than half (60%) of cases showed improved renal function and dialysis dependence was shown in 30% of cases.

Cui et al. compared clinical and laboratory data of patients suffering anti-GBM disease associated with depositions of immune complexes (10 cases) with data from anti-GBM disease alone (37 cases). No significant differences in clinical and pathological findings were observed. In comparison with anti-GBM disease associated with depositions of immune complexes reported by Cui et al., this present review of cases with concurrent anti-GBM disease and IgA nephropathy showed a tendency of better prognosis. Symptoms of oliguria were reported less commonly in concurrent anti-GBM disease and IgA nephropathy (10%) than in anti-GBM disease with immune complexes (40%). Percentage of crescent formation in cases of concurrent anti-GBM disease and IgA nephropathy (59%) is less than that in cases of anti-GBM disease with deposition of immune complexes (93.8%). Dialysis independence was more frequent in concurrent anti-GBM disease and IgA nephropathy (60%) than in anti-GBM disease with immune complexes (10%).

The connection between anti-GBM disease and IgA nephrop-

GBM, glomerular basement membrane; PD, prednisolone.
athy is uncertain. IgA nephropathy is the most common immune complex–mediated GN and clinical features vary from asymptomatic hematuria to RPGN.13 Occurrence of anti-GBM disease superimposed on underlying symptomatic IgA nephropathy could be a possible explanation. No cases were confirmed as IgA nephropathy before diagnosis of anti-GBM nephritis in the present review; however, a history of upper respiratory tract infection or microscopic hematuria was noted in some cases. Pathological changes of GBM components triggered by IgA-related immune complex deposition is another hypothesis.14 Anti-GBM antibodies might alter the permeability of GBM to allow circulating immune complex deposition in the mesangium.2

Based on the present review of a limited number of cases, concurrent anti-GBM disease and IgA nephropathy seems to have a better prognosis than anti-GBM disease alone or anti-GBM disease with immune complexes. In order to understand concurrent anti-GBM disease and IgA nephropathy as more than just a simple coincidence of the two diseases, more cases need to be analyzed with an in-depth examination of underlying pathogenic relationships between anti-GBM disease and IgA nephropathy.

**REFERENCES**

Ectopic hamartomatous thymoma (EHT) is a rare tumor which occurs almost exclusively in the supraclavicular or suprasternal area. Since first described by Smith and McClure in 1982,1 EHT has been reported in a total of 81 cases, which were mostly benign tumors. However, very rarely, a malignant tumor occurs in EHT, and only four cases have been reported.2-4 We report a case of a 52-year-old man with adenocarcinoma arising from EHT.

CASE REPORT

A 52-year-old man visited the hospital with a 1-year history of a supraclavicular mass which had grown to a size of 4 cm over the past 3–4 months. The radiologic findings on contrast-enhanced T1 weighted oropharynx magnetic resonance imaging showed a well-defined enhancing mass involving the left pectoralis major, suggesting a neurogenic tumor, complicated dermoid cyst or a reactive lymphadenopathy. Surgical removal was performed for diagnostic and therapeutic purposes. There has been no evidence of recurrence or metastasis in 6 months of follow up.

Grossly, the resected mass measured 3.1 × 3.1 × 1.8 cm. On section, the cut surface showed a well-circumscribed, multi-lobulated, whitish-gray, heterogenous, solid mass with focal cystic changes (Fig. 1A).

Microscopically, the tumor could be largely divided into two portions. The periphery of the tumor displayed a haphazard blending of epithelial and spindle cells with focal adipose tissue (Fig. 1B). The dominant portion was spindle cell proliferation with moderate cellularity. These cells were arranged in a fascicular and storiform pattern with oval-to-tapered nuclei with eosinophilic cytoplasm. There was no evidence of significant atypia or mitotic activity. Some small lymphocytes were admixed with the spindle cell component. There were also epithelial islands consisting of elongated strands or anastomosing networks, and some cystic spaces with focal squamous differentiation. These islands were perceptibly merged into spindle cells. Small amounts of mature adipocytes were scattered in various portions of the tumor.

In the central portion of the tumor, areas of atypical glandular proliferation forming solid and cribriform architecture with an infiltrative edge were identified (Fig. 1C). The cells were oncocytoïd with abundant, granular, eosinophilic cytoplasm, which are findings consistent with the features of apocrine cells and bearing some resemblance to ductal-type carcinoma. Unlike cells of the tumor periphery, the cells of the central portion had large pleomorphic nuclei with coarse chromatin and prominent nucleoli (Fig. 1D). Mitotic figures were identified and counted at an average of 3/high-power field, but atypical mitoses were not found.

On immunohistochemistry, both spindle cells and epithelial cells in the benign portion were reactive with pan-cytokeratin. The delicate spindle cells were positive for CD34, but negative for S-100. Both the spindle cells and the epithelial components of all areas of the tumor showed nuclear staining for androgen receptor (Fig. 1E).

EHT shows a biphasic pattern, so our differential diagnosis included other malignant lesions. Based on the CD34 and S100 immunohistochemistry results, we excluded synovial sarcoma and malignant peripheral nerve sheath tumor with epithelial differentiation. The tumor did not have chondromyxoid stroma,
which can distinguish EHT from mixed tumor of the skin. Notably, the dysplastic area showed complete and circumferential intense membrane staining of human epidermal growth factor receptor 2 (HER2) and scored 3+ in accordance with the HER2 analysis criteria for breast cancer (Fig. 1F). HER2 gene amplification was not performed.

Because the lesion had recently grown in size and the histological features showed a distinct malignant area with typical

**Fig. 1.** Representative images of adenocarcinoma arising in ectopic hamartomatous thymoma (EHT). (A) Gross findings show a well-circumscribed, multi-lobulated, whitish-gray, heterogenous, solid mass with focal cystic changes. (B) The periphery of the tumor is composed of epithelial cells, spindle cells and adipose tissue, typical features of EHT. (C) The area of atypical glandular proliferation (right) is distinct from the background EHT (left). (D) The malignant components have large pleomorphic nuclei with prominent nucleoli and abundant eosinophilic cytoplasm. (E) Androgenic receptor immunostain shows nuclear positivity in both the benign and malignant areas. (F) HER2 overexpression is only identified in the malignant portion (right).
EHT, we diagnosed this tumor as an adenocarcinoma arising in EHT.

Ethics statement

This report was approved by the Institutional Review Board of Korea University Anam Hospital (2018AN0340), and informed consent was waived.

DISCUSSION

EHT is a rare tumor, and only 81 cases have been reported thus far. It is generally known as benign, but there have been a few reports of malignancy.\(^2\)\(^-\)\(^3\) Three malignant cases had a portion of EHT with a distinct adenocarcinoma component. Consistent with these three cases, the present case demonstrated an area of atypical glandular proliferation with a punctuated cribiform or solid architecture where infiltration was identified, which was diagnosed as invasive adenocarcinoma arising in EHT.

According to the literature, a relatively high prevalence of HER2 overexpression was reported in ductal-type carcinoma ex pleomorphic adenoma,\(^5\) and HER2 overexpression was only restricted to the malignant portion.\(^6\) Also, the HER2 positivity was closely related to the aggressive behavior of carcinoma ex pleomorphic adenoma.\(^5\) These findings suggest that HER2 overexpression had an important role in the malignant transformation of pleomorphic adenoma and progression of carcinoma ex pleomorphic adenoma. Likewise, we could suggest that HER2 overexpression may explain the morphological similarity of the malignant area to ductal-type carcinoma (e.g., pleomorphic and oncocytic tumor cells), and HER2 might have a potential role in the malignant transformation of EHT.

One previous report associated EHT with the androgenic receptor.\(^7\) This implies that EHT is a tumor affected by androgenic stimuli and is further supported by the fact that EHT occurs exclusively in the adult male.\(^7\) Moreover, as the androgenic receptor was positive in both the benign and malignant areas of the tumor, we can suggest that the androgenic receptor is related to the occurrence of EHT.

To the best of our knowledge, this is the first case in which HER2 overexpression was found in a malignancy arising in EHT. Patients with HER2 overexpression have a therapeutic advantage because of the availability of targeted therapy, such as trastuzumab, once the mutation is confirmed. Therefore, identification of HER2 overexpression in adenocarcinoma arising from EHT could not only provide important information for understanding the pathogenesis of malignant transformation of EHT, but it can also indicate treatment with trastuzumab as a potential therapeutic target agent.

Primary large cell neuroendocrine carcinoma (LCNEC) of the endometrium is extremely rare\(^1\)\(^2\) and the cytomorphology has not been well described. Recently, we experienced a case of combined LCNEC with endometrioid carcinoma (ECa) showing peritoneal dissemination that was confirmed by histology and peritoneal fluid cytology. The purpose of this report is to delineate cytologic characteristics of LCNEC in an effusion specimen.

**CASE REPORT**

A 62-year-old woman was admitted for evaluation of continuous vaginal bleeding for 1 month. She was in a menopausal state since the age of 50 years with gravida 2-para 2, and had no specific remarkable past medical history. Her initial laboratory test was unremarkable. Ascites was noticed on physical examination. On ultrasonography, the uterine corpus was enlarged with the endometrium thickened to 15 mm. Endometrial curettage showed low-grade ECa. Intraoperative peritoneal fluid sampling demonstrated small-sized tumor cell clusters measuring approximately 100–150 μm in diameter and discohesive polyhedral single tumor cells admixed with karyorrhectic debris, which made a definitive diagnosis difficult. In contrast to mesothelial cells and lymphocytes in the background, tumor cells had large nuclei with an irregular nuclear membrane, vesicular nuclei, relatively prominent nucleoli, and notable cytoplasm (Fig. 1A–C). A panel of immunohistochemical stains was performed on the cell block material, and atypical cells were positive for CD56 (Fig. 1D) and synaptophysin, but not for chromogranin and CD45. These findings were consistent with neuroendocrine carcinoma (NEC). An en-bloc resection was performed. On microscopic examination, there were foci of transition between a low-grade ECa and a loosely cohesive carcinoma component in the endometrium (Fig. 2A) invading the superficial myometrium (Fig. 2B). The loosely cohesive tumor component showed pseudoglandular and cord-like growth patterns. The tumor cells had relatively abundant cytoplasm, vesicular nuclei, and prominent nucleoli (Fig. 2C). There were tumor emboli in lymphovascular spaces of the myometrium. These cells were positive for CD56 (Fig. 2D) and synaptophysin (Fig. 2E), but negative for CD45 and CD99. Some tumor cells were positive for epithelial membrane antigen (Fig. 2F) and cytokeratin. According to these findings, a diagnosis of combined LCNEC with a low-grade ECa was made. The patient died of the disease 32 days after operation.

**Ethics statement**

Approval for this case report was obtained from the Institutional Review Board (IRB) of Chungnam National University Hospital (CNUH-IRB 2017-9-49) with a waiver of informed consent.

**DISCUSSION**

LCNEC is characterized by the presence of polygonal cells with a neuroendocrine growth pattern in at least part of the tumor and expression of one or more of the neuroendocrine markers (chromogranin, CD56, and synaptophysin) in more than 10%
of tumor cells.\textsuperscript{1} Due to the rarity of LCNECs in the female genital tract,\textsuperscript{1-3} a specific diagnosis of LCNEC is usually not possible in effusion specimens. Additional difficulties that may be encountered in effusion cytology include overlapping morphology among similar neoplastic entities, scant cellularity, and predominance of apoptosis or cellular debris. Cytopathologic diagnosis of LCNEC is more challenging than small cell neuroendocrine carcinoma due to rare nuclear molding (13\%), frequent apoptosis (67\%), and prominent nucleoli (86\%) in LCNEC.\textsuperscript{4} The cytologic findings of LCNEC of the uterine cervix are characterized by loosely cohesive clusters or single tumor cells with hyperchromatic nuclei and necrotic materials in the background. The ovoid nuclei are 3–5 times larger than nuclei of small lymphocytes and have coarsely clumped chromatin and two or more prominent nucleoli. The tumor cells have a moderate amount of cytoplasm.\textsuperscript{5-7}

A cytopathologic differential diagnosis of our case included serous carcinoma, small cell NEC (SCNEC), and undifferentiated carcinoma. Serous carcinoma is characterized by marked exfoliation of high-grade tumor cells either in the form of cellular clusters or single cells. Psammoma bodies can be seen.\textsuperscript{8} SCNEC is composed of relatively uniform small hyperchromatic nuclei with characteristic nuclear molding and scant cyanophilic cytoplasm.\textsuperscript{9} In this case, cellular overlapping, an acinar arrangement, and papillary configuration were not distinctive. Dedifferentiated carcinoma is composed of a mixture of undifferentiated carcinoma and either the International Federation of Gynecology and Obstetrics grade 1 or 2 ECa.\textsuperscript{1} Undifferentiated carcinoma grows as sheets of noncohesive atypical tumor cells without any nested or trabecular architecture and displays chromogranin and/or synaptophysin staining in a minority of tumor cells.\textsuperscript{10} In this case, the tumor components showed a cord-like growth pattern and were positive for CD56 and synaptophysin.

In high-grade NEC metastases, the three architectural patterns of the cytomorphologic spectrum that have been presented within body cavities are (1) a predominance of small clusters of tumor cells (seen more often in LCNEC cases), (2) a predominance of large clusters of tumor cells (mainly in SCNEC), and (3) a predominance of single tumor cells (seen in both SCNECs and LCNECs).\textsuperscript{1} The small clustering pattern is seen in 73\% of LCNEC and 41\% of SCNEC cases.\textsuperscript{4} Our case presented predominantly with small clusters of tumor cells measuring less

Fig. 1. Cytologic features of large cell neuroendocrine carcinoma in a peritoneal fluid smear. (A) Loose clusters of tumor cells measuring 100 to 150 μm are present. (B, C) These tumor cells are polyhedral with abundant eosinophilic cytoplasm, nuclei are either vesicular or hyperchromatic, chromatin is heterogeneous, and nucleoli are variably prominent. (D) These cells show positive reactions for CD56.
than 150 μm (approximately 100 to 150 μm) and discohesive single tumor cells.

Dear Editor,

With great interest, we read the article “Prognostic Role of Claudin-1 Immunohistochemistry in Malignant Solid Tumors: A Meta-Analysis”.¹ The authors stated that low claudin-1 immunohistochemistry expression is significantly correlated with worse survival in various malignant tumors. The results of the meta-analysis are encouraging. Nevertheless, there are still some shortcomings that need to be addressed.

Firstly, literature search is an important step in meta-analysis. If the collection is incomplete, it will lead to obvious selective bias. I want to know whether this is an independent collection in the process of literature collection and how the authors resolved the differences of opinion.

Secondly, the authors seem to have forgotten the key step: quality assessment. We doubt the quality of the attached literature. If the quality of the literature is poor, it will directly affect the value of the results.

Finally, overall survival and disease-free survival are two key endpoints. The authors point out that to avoid bias, articles with a follow-up date of 60 months were extracted. So we want to know if literature collection excluded articles that had follow-up period less than 60 months. Also, we want to know that the overall survival rate and disease-free survival rate refer to the 5-year survival rate? If not, we recommend that it be shown in the text or table.

Nevertheless, we are grateful to the authors for their efforts in studying the association between claudin-1 immunohistochemistry and malignant solid tumors.

This study aimed to elucidate the prognostic roles of claudin-1 immunohistochemistry in various malignant tumors through a meta-analysis. Data from all included studies were extracted by two independent authors (J.S.P. and N.Y.K.). Any disagreements for extracting data were resolved by consensus. In the present study, to review more articles, we used the narrow exclusion criteria. Therefore, discordance for the literature collection did not occur. We assessed the risk of bias for all included studies according to the Newcastle-Ottawa Scale. The detailed information was shown in Table 1. All data for survivals were a 5-year survival rate. If the extractable data only included the survival curve, survival rates at 5-year were obtained from the survival curve.
